After a median sternotomy is made, the pericardium is incised and attached to the wound edges. Typically, the right heart is enlarged, with a tense RA and a variable degree of tricuspid regurgitation. There is usually severe RV hypertrophy. These patients are generally quite sensitive to any manipulation of the heart, and with critical degrees of obstruction, the patient's condition may become quite unstable. Anticoagulation is achieved with the use of heparin (400 units/kg, intravenously) administered to prolong the activated clotting time beyond 400 seconds. Full CPB is instituted with high ascending aortic cannulation and two caval cannulae. The heart is emptied on bypass, and a temporary pulmonary artery vent is placed in the midline of the main pulmonary artery 1 cm distal to the pulmonary valve. When CPB is initiated, surface cooling with both the head jacket and the cooling blanket is begun. The blood is cooled with the pump-oxygenator. Cooling generally takes 45 minutes to 1 hour. When ventricular fibrillation occurs, an additional vent is placed in the LV through the right superior pulmonary vein. This prevents atrial and ventricular distention from the large amount of bronchial arterial blood flow that is common with these patients. Fig. 114.4 shows the typical instruments used during PTE surgery, and Fig. 114.5 shows the operative setup and the RPA exposure.

Typically, the primary surgeon starts the operation standing on the patient's left side. During the cooling period, some preliminary dissection can be performed, with full mobilization of the RPA from the ascending aorta. The SVC is also fully mobilized. The approach to the RPA is made medial, not lateral, to SVC. All dissection of both pulmonary arteries takes place intrapericardially, and neither pleural cavity is entered. An incision is then made in the RPA from beneath the ascending aorta out under the SVC, entering the lower lobe branch of the RPA. It is important that the incision stays in the center of the vessel and continues into the lower rather than the middle lobe artery.

When the patient's temperature reaches 20°C, the aorta is cross-clamped, and a single dose of mixed blood Del Nido cold cardioplegia (1 L) is administered. Several centers use a cooling jacket for additional myocardial protection. The entire procedure is now performed with a single aortic cross-clamp period with no further administration of cardioplegic solution.

A modified cerebellar (or a Madani PTE) retractor (the "J" instrument shown in Fig. 114.4) is placed between the aorta and SVC, as shown in the Fig. 114.5 insert. Upon opening the RPA, a varying degree of loose thrombus may be present, which can be removed to ensure good visualization of the vascular bed. It is important to recognize, however, that first, an embolectomy without subsequent endarterectomy is quite ineffective, and second, in most patients, initial examination of the pulmonary vascular bed shows no obvious thrombotic material. Therefore, to the inexperienced or cursory glance, the pulmonary vascular bed may appear normal even in patients with severe CTEPH. Fig. 114.6 shows the typical findings within the pulmonary artery of a patient with CTEPH.

If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before arrest, it is unwise to proceed unless perfect visibility is obtained. Recognizing the correct plane of dissection is perhaps the most crucial and challenging part of this operation. When blood obscures direct vision of the pulmonary vascular bed, propofol is administered (200 mg) until the electroencephalogram becomes isoelectric. In most cases, the electroencephalogram is already isoelectric when the core temperature reaches 20°C. DHCA is then initiated, and the patient undergoes exsanguination. It is rare that one 20-minute period for each side is exceeded. Although retrograde and low-flow antegrade cerebral perfusion techniques are used for DHCA in other procedures, they are not helpful in PTE because they do not allow a completely bloodless field,[102] and with the short DHCA times that can be achieved with experience, it is not necessary.

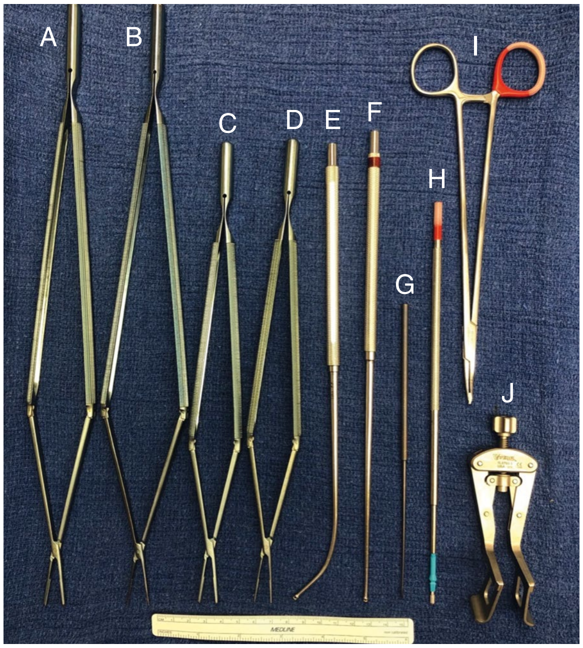

FIGURE 114.4 PTE instrument set: (A) 16″ double-action Madani PTE forceps with 2.5-mm tip; (B) 16″ double-action Madani PTE forceps with 1-mm tip; (C) 12″ double-action Madani PTE forceps with 2.5-mm tip; (D) 12″ double-action Madani PTE forceps with 1-mm tip; (E) modified curved Jamieson PTE suction/dissector; (F) modified Jamieson PTE suction/dissector; (G) Micro-Penfield 4 dissector; (H) fine beaver blade; (I) "mini-nut" dissector—small 7-mm by 3-mm by 1-mm PTFE buttress pledget in a 10″ tonsil clamp; (J) Madani PTE retractor. *PTE,* Pulmonary thromboendarterectomy; *PTFE,* polytetrafluoroethylene.

A microtome knife is used to develop the endarterectomy plane posteriorly because any inadvertent egress in this site could be repaired readily or simply left alone. The endarterectomy is then performed with an eversion technique. It is important that each subsegmental branch is followed and freed until it ends in a "tail" beyond which there is no further obstruction. Residual material should never be cut free; the entire specimen should "tail off" and come free spontaneously. Upon inspection and endarterectomy, one may encounter several signs of chronic thromboembolic obstruction, such as webs, pouches, complete occlusions, or just merely thickened intima (see Fig. 114.6).

After the right-sided endarterectomy is completed and before initiation of bypass, a bubble test is performed to identify any potential vascular injury.[103] Although rare in experienced hands, a continuous stream of bubbles with a peak inspirator pressure of 25 to 30 cm H_2O is quite concerning for postoperative airway hemorrhage and should be carefully investigated while on circulatory arrest and appropriately dealt with.[104] Circulation is then restarted, and the arteriotomy is closed with a continuous 6-0 polypropylene suture.

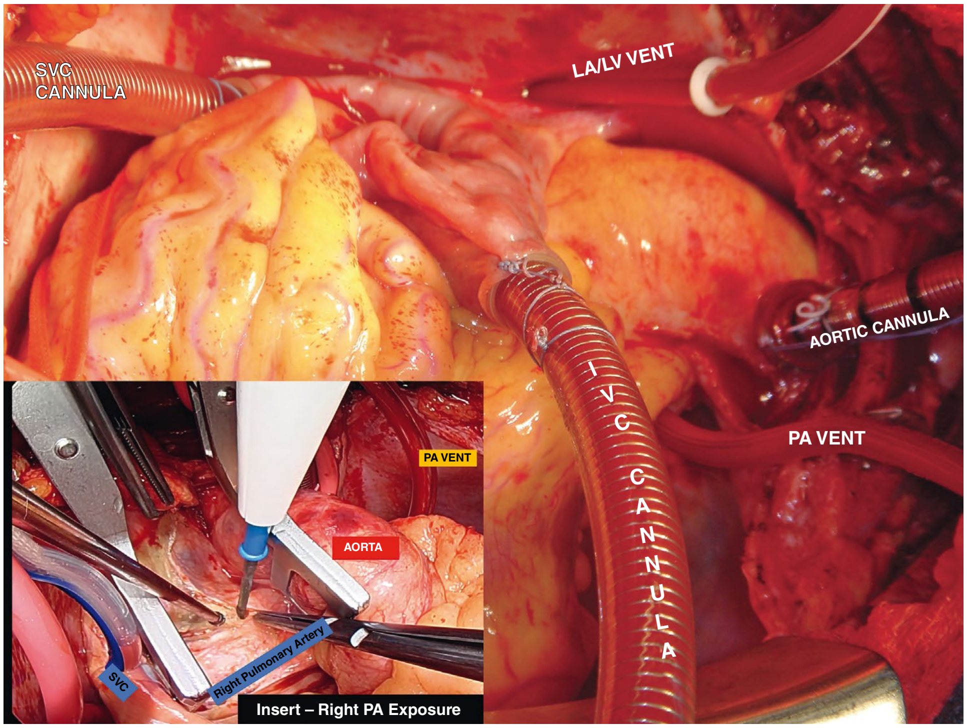

FIGURE 114.5 Operative field setup and view. Typically, the SVC and IVC cannulae are crossed for easier initiation of bypass, without manipulating the right heart. The *insert* figure shows the exposure of the right pulmonary artery between the aorta and SVC. *IVC*, Inferior vena cava; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *SVC*, superior vena cava.

Occluded Middle Lobe Artery

FIGURE 114.6 Typical chronic thromboembolic pulmonary hypertension findings within the pulmonary artery. Aorta is retracted medially to the left side.

Then, the surgeon moves to the patient's right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made from the site of the pulmonary vent hole laterally to the pericardial reflection, avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, may endanger the left phrenic nerve, and makes subsequent repair of the left pulmonary artery more difficult. The left-sided dissection is virtually analogous in all respects to that accomplished on the right, and the duration of DHCA intervals is subject to the same restrictions.

After the completion of the endarterectomy, CPB is reinstituted, and warming is commenced. The rewarming period generally takes approximately 90 to 120 minutes, but it varies according to the body mass of the patient. Then, the pulmonary artery is closed, and the pulmonary vent is replaced. If there is evidence of patent foramen ovale or atrial septal defect, the RA is then opened, and any interatrial communication is closed. Although tricuspid valve regurgitation is variable in these patients and can be severe, tricuspid valve repair traditionally has not been performed. The rationale is that RV remodeling occurs within a few days, with the return of tricuspid competence.[105,106] However, in the long term, tricuspid regurgitation may recur despite a complete endarterectomy. We typically repair tricuspid valves when the regurgitation is severe and/or if the annulus is larger than 4 cm. Clearly, any leaflet damage, such as that seen from pacemaker leads, will require repair. Intracardiac pacemaker leads in CTEPH patients should be carefully examined and, in most cases, exchanged for epicardial leads.

If other cardiac procedures are required, such as coronary artery or mitral or aortic valve surgery, these are conveniently performed during the systemic rewarming period.[95,98] Myocardial cooling is discontinued after all cardiac procedures have been concluded. The left atrial vent is removed, and the vent site is repaired. All air is removed from the heart, and the aortic cross clamp is removed. When the patient has fully rewarmed, CPB is discontinued. Dopamine hydrochloride is routinely administered at renal doses, and other inotropic agents and vasodilators are titrated as necessary to sustain acceptable hemodynamics. The CO is generally high, with a low systemic vascular resistance. Temporary atrial and ventricular epicardial pacing wires are placed.

Despite the duration of extracorporeal circulation, hemostasis is readily achieved, and the administration of blood products and coagulation factors is generally not indicated and unnecessary. Wound closure is routine. A vigorous diuresis is usual for the next few hours, also a result of the previous systemic hypothermia.

Thromboembolic Surgical Classification

A recent intraoperative classification of the disease (levels 0–IV), as shown in Table 114.4, was developed and described by the UC San Diego group. The classification categorizes pulmonary thromboembolism in CTEPH into levels based on the location of the fibrotic thromboembolic material.[107–109]

TABLE 114.4 **University of California, San Diego, Chronic Thromboembolic Disease Surgical Classification**[a]

Level 0 (R/L)	No evidence of chronic thromboembolic disease
Level I (R/L)	Chronic thromboembolic disease encountered in the main pulmonary artery
Level I C (R/L)	Complete occlusion of one main pulmonary artery with thromboembolic disease
Level II (R/L)	Chronic thromboembolic disease starting at the level of lobar arteries or in the main descending pulmonary arteries
Level III (R/L)	Chronic thromboembolic disease starting at the level of the subsegmental arteries
Level IV (R/L)	Chronic thromboembolic disease starting at the level of the segmental arteries

[a] The classification is based on the most proximal disease identified in each pulmonary artery and is designated R (for the right lung) and L (for the left lung).

There are four levels of pulmonary occlusive disease related to thrombus that can be appreciated: level 1, involving the main pulmonary arteries; level 2, starting at the lobar branches; level 3, starting at the segmental branches; and level 4, where disease is only encountered at the subsegmental branches. In addition, level 1C indicates complete occlusion of one lung with total obstruction of the main right or left pulmonary artery, and level 0 indicates no evidence of CTEPH in the corresponding lung. Furthermore, the presence or absence of fresh thromboembolic material does not have any bearing on the classification. In other words, presence of stasis clot would no longer upgrade the surgical level of the disease. Fig. 114.7 shows a typical specimen removed from a patient with bilateral level 1 disease, and Fig. 114.8 shows a typical specimen removed from a patient with level 3 disease. The corresponding pulmonary angiogram and typical radiographic signs are also highlighted.

It is important to note that this is a surgical classification as encountered at the time of endarterectomy. As imaging modalities improve, the ability to predict the level of disease preoperatively has improved; however, invariably, more disease is encountered at the time of surgery than predicted on routine imaging preoperatively. Notably, greater technical expertise is required for level III to IV disease resection with higher complications, but hemodynamic improvement can still be expected after successful surgery.

Postoperative Care

Meticulous postoperative management is essential to the success of this operation. Although much of the postoperative care is common to that of the more ordinary open-heart surgery patients, there are some important differences.

First, all patients are mechanically ventilated for at least 24 hours. In general, there is more occlusion on the right side, and both lower lobes are more affected than the upper lobes. Restored blood flow after PEA is ordinarily disproportionately directed toward the lower lobes and to the right. Adequate ventilation of both lower lobes is necessary to avoid a low ventilation-perfusion ratio after the operation. In addition, higher minute ventilation is often required early after the operation to compensate for the temporary

metabolic acidosis that develops after the long period of circulatory arrest, hypothermia, and CPB. Extubation should be performed on the first postoperative day, if possible.

Second, all patients are subjected to a maintained diuresis with the goal of reaching the patient's preoperative dry weight within the first 24 hours. Patients are in considerable positive fluid balance after operation because of perioperative fluid administration, the administration of fluid from the bypass circuit, and the tendency of the patient to retain fluid during profound hypothermia. Patients initiate an early, spontaneous aggressive diuresis, but this should be augmented with diuretics.

ECG, systemic and pulmonary arterial and central venous pressures, temperature, urine output, arterial oxygen saturation, chest tube drainage, and fluid balance are monitored. A pulse oximeter is used to continuously monitor peripheral oxygen saturation. Management of cardiac arrhythmias and output and treatment of wound bleeding are identical to those for other open-heart operations.[101]

Complications

Not only are patients after PTE subject to all complications associated with open-heart and major lung surgery (arrhythmias, atelectasis, wound infection, pneumonia, mediastinal bleeding, etc.), but also specific complications may arise. One such complication is the development of a "reperfusion response." This is a specific complication that occurs in most patients to some degree and is related to localized pulmonary edema. Reperfusion pulmonary edema is a phenomenon in which endarterectomized and reperfused areas of lung develop a high-permeability edema.[110] Severe cases can cause airway hemorrhage, which can also occur because of trauma during surgical dissection, friability of endarterectomized vessels, and bleeding from systemic-to-pulmonary collateral arteries. Both reperfusion pulmonary edema and airway hemorrhage are associated with increased mechanical ventilation days, length of stay, and mortality.[110] Treatment remains supportive, including use of an extracorporeal membrane oxygenator.[111,112]

Residual PH, although not defined precisely, is also associated with high perioperative mortality.[113] The role and timing of rescue pharmacotherapy, balloon pulmonary angioplasty (BPA), or both in patients with severe residual PH are not well defined.

Severe airway bleeding should be managed, if possible, by identification of the affected area by bronchoscopy and balloon occlusion of the affected lobe until coagulation can be normalized.[104] ECMO can be very helpful in managing airway bleeding.[104,114] Hemoptysis from a bronchial collateral can be unique because airway bleeding starts with bright-red blood while the patient is still on full CPB with no forward pulmonary flow. It is rare to require bronchial artery embolization, but this is occasionally required if ongoing systemic airway bleeding ensues. In contrast, the amount of airway bleeding secondary to vessel wall injury directly correlates with the amount of pulmonary artery flow and will be at its worst upon termination of bypass.

Surgical Advancements

Over the last decade, several innovations have enhanced surgical techniques and approach. Perhaps the most important advancement has been redefining the limits of distal endarterectomy. In expert centers, PTE can be successfully performed in patients with distal disease. This is attributed to advances in imaging, techniques, instruments, and surgical experience. Depending on the level of experience of a center, operability may vary. A new definition of expert center has been proposed as the following: availability of all treatment modalities

(PTE, BPA, medical therapy), surgical volume >50 cases per year, the ability to perform segmental endarterectomy, and surgical mortality <5%.[88]

There have now been over 5000 PTE surgeries at UC San Diego, and almost all of these have been carried out since the early 1990s. The mortality is now in the range of 1% to 1.5%, with sustained benefit.

Based on advances in cardiac surgery, minimally invasive techniques for PTE have been developed at UC San Diego. Using preoperative CT for surgical planning, the procedure is performed using the second or the third intercostal space through bilateral or unilateral mini–anterior thoracotomies approximately 4 to 5 cm in length. The ideal location of the incisions is both high enough for central aortic cannulation yet low enough for access to the pulmonary arteries. This typically is in the second intercostal space. The arterial cannula is placed centrally in the ascending aorta, and venous cannulae are placed in the femoral vein, RA, and/or right internal jugular vein. For all these patients, cardioplegia and cross clamp are not used for purposes of simplification and to maximize space. An aortic root vent is intermittently used just before going back on CPB with each circulatory arrest. Pulmonary artery and left atrial vents are used. The usual protocol for circulatory arrest and exposure of the pulmonary arteries is used. The minimally invasive approach to PTE surgery is not appropriate for patients with unsuitable chest anatomy; those with severe right heart failure, especially in the setting of distal disease; or those who are undergoing concomitant cardiac procedures.[99,115]

Multimodality Treatment Options

Over the past decade, although a wide variety of medical therapies have become available for the treatment of CTEPH, including pulmonary artery hypertensive (PAH), the appropriate use and efficacy of such medical treatments has not been clearly defined in CTEPH. PTE surgery has been the only curable treatment available for patients with CTEPH.[113,116,117] However, the first international CTEPH registry found that around 36.4% of all CTEPH patients were deemed by the clinicians to be inoperable.[81] According to the new worldwide prospective CTEPH registry from the data of 1010 newly diagnosed consecutive patients, reasons for PEA inoperability were technical inaccessibility ($n = 235$), comorbidities ($n = 63$), and patient refusal ($n = 44$).[118] Because of poor long-term survival rates in inoperable patients, with 70% at 3 years compared with 89% in operable patients,[119] determination of operability is of paramount importance. For those who are truly inoperable, both medical therapy and BPA are available.[88,96,109] Fig. 114.9 highlights the site of action for the three different modalities.

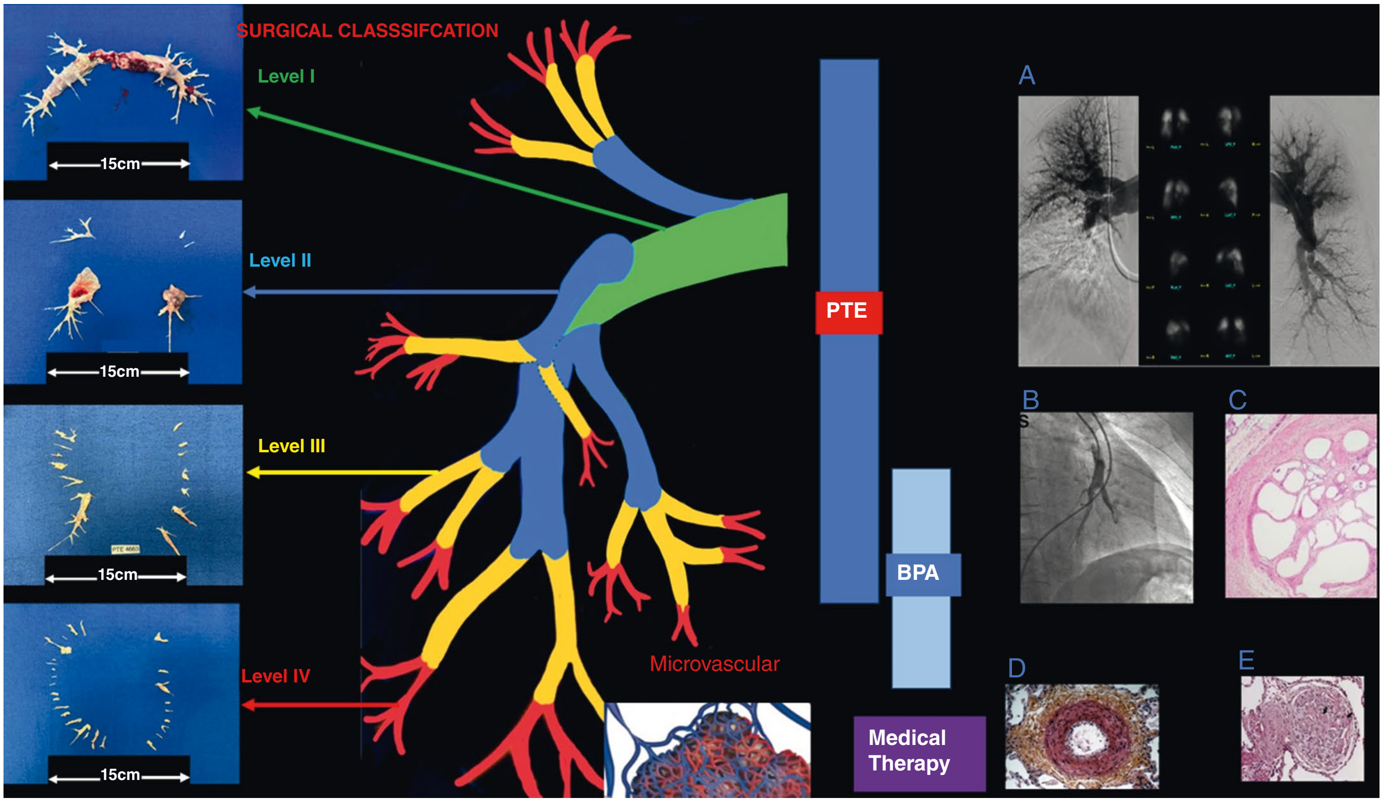

FIGURE 114.9 Treatment options for CTEPH target different pathogenic manifestations in different parts of the pulmonary vascular bed. (A) Perfusion scan and pulmonary angiogram of typical CTEPH patient. (B) Selective pulmonary angiogram of segmental and subsegmental pulmonary arteries, showing irregular vessel contour and occlusion, typical of CTEPH. (C) Microscopic examination showing a luminal filling defect with recanalized chronic thrombus (web lesion) and no evidence of vasculopathy in the subsegmental artery. (D) Intimal fibromuscular proliferation. (E) Plexiform lesion and vessel occlusion resulting from vasculopathy and proliferation. *BPA,* Balloon pulmonary angioplasty; *CTEPH,* chronic thromboembolic pulmonary hypertension; *PTE,* pulmonary thromboendarterectomy.

Medical Therapy

Riociguat and subcutaneous treprostinil are currently approved medical therapies for CTEPH. Riociguat is a soluble guanylate cyclase stimulator. Impairment of nitric oxide synthesis and signaling through the nitric oxide–soluble guanylate cyclase–cyclic guanosine monophosphate pathway is involved in the pathogenesis of PH. Riociguat has a dual mode of action, directly stimulating soluble guanylate cyclase independently of nitric oxide and increasing the sensitivity of soluble guanylate cyclase to nitric oxide. Riociguat increases the level of cyclic guanosine monophosphate, resulting in vasorelaxation and antiproliferative and antifibrotic effects.[120] Treprostinil is a prostacyclin. It reduces PAP and PVR by inhibiting the contraction of the pulmonary artery.[121]

Balloon Pulmonary Angioplasty

BPA was popularized in Japan in 2012,[122,123] mainly as a result of the lack of high-volume expert PTE centers. It is now being used with increasing frequency for inoperable patients in expert centers. BPA is less invasive, does not require anesthesia, and involves using angiographically directed wires and balloons to widen stenotic lesions and break up webs and bands in distal vessels to restore blood flow. BPA showed the improvement of symptoms and hemodynamics in inoperable patients. It has been established to address peripheral targets because the main reason for inoperability is surgical inaccessibility and comorbidities.[124–128] About 10% of patients have complications during the BPA procedure.[129,130] Vascular injury with or without hemoptysis by wire perforation or balloon overdilatation, high-pressure contrast injection, vascular dissection, allergic reaction to contrast, and adverse reaction to conscious sedation or local anesthesia, among other complications, may occur. After the procedure, lung injury (radiographic opacity with or without hemoptysis, with or without hypoxemia), renal dysfunction, or access site problems may also occur.[88]

BPA has been shown to provide improvement in symptoms and quality of life, with relatively low risk of complications in expert centers. However, BPA requires multiple sessions and generally carries a high risk of vessel perforation, especially in completely occluded vessels. Importantly, interventional treatment of more proximal lesions (= surgically accessible) leads to worse outcomes.[131] Furthermore, because the disease is left behind and the vessel compliance remains abnormal, patients continue to have diminished exercise tolerance despite improved hemodynamic numbers at rest.[132] Furthermore, the long-term consequences for patients who undergo BPA yet have unresolved residual thromboembolic disease are unknown.

Perioperative Medical Therapy or Balloon Pulmonary Angioplasty

Because complete relief of the pulmonary vasculature can only be achieved by surgery, PTE remains the treatment of choice.[96,109] However, borderline cases with severe hemodynamic impairment might be addressed by multimodal strategies aiming to reduce the risk of surgery. Multimodal treatment concepts may be beneficial in certain patients, but thorough evaluation and decision-making by an experienced multidisciplinary team is mandatory. These are the scenarios that the specialists may encounter:

1. Although there is no approved drug for operable CTEPH, medical pretreatment is regularly seen even before evaluation at an expert center, usually leading to a delay of (potentially curative) surgery.[81,118,133] Perioperatively, inhaled iloprost is used in some centers.[134,135] For residual PH after PTE, both riociguat and treprostinil are approved.[120,121]
2. BPA of certain subsegmental disease, which is likely to be inaccessible for the surgeon, might also be a strategy in unique patients; however, the approach is not universally adopted in experienced centers. Recently, in a proof-of-concept study in nine selected CTEPH patients with mixed (proximal and distal) anatomic lesions and high preoperative PVR (PVR >800 dynes·sec·cm^{-5}), sequential multimodal therapy combining medical treatment, BPA, and PTE was found to be a safe and effective option.[136] However, evidence supporting this approach remains scarce.
3. The combination of intraoperative BPA in surgically inaccessible regions has been described but remains a single-center experience.[129] BPA for residual/recurrent PH after PTE appears promising, with growing evidence.[130,137,138]

Outcomes

Like other major cardiac procedures, there has not been an RCT of PTE surgery versus other treatment options. However, there are multiple published large case series that demonstrate the effectiveness of PTE with respect to hemodynamic outcomes, with two reporting over 2000 consecutive patients.[116,139] The degree of reduction in mPAP and PVR was comparable and greater than that demonstrated by medical treatment and BPA. In the largest series published, from UC San Diego, there was a reduction in PVR from 719 to 253 dynes·sec·cm^{-5} in the most recent 500-patient cohort. Carefully controlled studies have confirmed no deterioration in cognitive function postsurgery despite the requirement for DHCA.[102]

Over time, successive large series have also demonstrated a reduction in perioperative mortality, with an in-hospital mortality of 2.2% for the latter reported cohort[116] and a 30-day mortality of 1.9% for a more contemporary cohort from the Cambridge group.[139] International registries have also shown a reduction in mortality. The initial international registry reported an in-hospital mortality of 4.7%,[113] with the most recent international registry reporting 3.5% mortality after PTE.[118] The use of ECMO has allowed salvage of patients with the most severe complications after surgery.[112]

The improvement in hemodynamic parameters after PTE has also led to functional and quality-of-life benefits for patients, and these are sustained at 5 years.[140] The improvement in perioperative outcomes has also translated into excellent long-term survival, with a national case series with the longest reported comprehensive follow-up demonstrating 86%, 84%, 79%, and 72% survival at 1, 3, 5, and 10 years, respectively.[141]

CONCLUSION

Acute PE is a common but life-threatening disease. It causes PH, RV dysfunction, and hypoxemia. Because symptoms and signs vary and there are no specific symptoms of acute PE, clinical diagnosis is often missed or falsely made. If patients have presentations suspicious for acute PE, it should be decisively investigated using all the tools available, including PE prediction scores, laboratory tests, and imaging modalities. The mortality of untreated PE is high, but it can be reduced by prompt and appropriate management. The specific treatment strategy is based on the classification for risk assessment. For hemodynamically unstable patients, respiratory and circulatory management in an intensive care unit under an expert team is the recommended approach.

The specific management for acute PE may include use of early anticoagulation, catheter-directed or systemic thrombolytic therapy, percutaneous suction thrombectomy, and surgical embolectomy. In certain patients, temporary use of ECMO may be helpful. Oral anticoagulation for more than 3 months is highly effective in preventing recurrent VTE; extended or indefinite anticoagulation should be considered in patients with cancer or coagulation disorders. Despite appropriate management, in about 1% to 5% of patients, prolonged symptoms, increased pulmonary pressures, and RV dysfunction persist, leading to CTEPH.

CTEPH is a unique form of PH (group 4) characterized by two-compartment disease, first as a direct result of unresolved thrombotic occlusion, often combined with a second compartment with concomitant and complex small-vessel arteriopathy. It is increasingly apparent that CTEPH is a more common condition than commonly recognized, and it carries a poor prognosis without treatment. The current approach to evaluation and treatment requires expertise from a multidisciplinary team working together to provide optimal treatment strategies. PTE (or PEA) surgery is the treatment of choice and can be potentially curative for patients with CTEPH. Although PTE is technically demanding for the surgeon, requiring careful dissection of the pulmonary artery planes and the use of DHCA, excellent short- and long-term results can be achieved. Successive improvements in operative technique developed over the last two decades now allow PTE to be offered to high-risk patients with a low mortality rate and anticipation of excellent clinical outcomes. Medical therapy and BPA have been shown to improve symptoms and function. They are generally reserved for patients with distal disease who are not surgical candidates or patients who suffer from residual PH after PTE. Increased understanding of both the prevalence of this condition and the possibility of a surgical cure and multimodality treatment options should avail more patients of the opportunity for relief from this debilitating and ultimately fatal disease. Although there is still more work to be done in the field of CTEPH treatment, it is important to make sure that patients with CTEPH are referred to experts who can provide them with a multimodal approach to treatment. The importance of expert referral for proper assessment and treatment strategy cannot be overemphasized.

SELECTED REFERENCES

Humbert M, Kovacs G, Hoeper MM, et al. 2022 ESC/ERS guidelines for the diagnosis and treatment of pulmonary hypertension. *Eur Heart J*. 2022;43:3618-731.

These are the latest guidelines by the ESC and the European Respiratory Society on management of PH. Although this is a comprehensive review of all major groups of PH, it still provides the latest and most up-to-date diagnostic and management strategies in relation to CTEPH. Furthermore, there is an updated and detailed diagnostic and treatment algorithm that readers will find quite helpful.

This scientific statement from the American Heart Association describes in detail the management and treatment of pulmonary embolism based on the severity and the size of the embolism and its impact in the acute setting. In addition, an overview of chronic thromboembolic pulmonary hypertension is also provided.

Jamieson SW, Kapelanski DP. Pulmonary endarterectomy. *Curr Probl Surg*. 2000;37:165-252.

This review is a landmark publication detailing the principles of pulmonary endarterectomy surgery in a step-by-step manner. The surgery was developed and pioneered at UC San Diego and has evolved over the years, but it is still followed very closely all around the world. Furthermore, this publication provided the principles of diagnosis, complications, and management strategies as practiced at UC San Diego, which continues to be a worldwide leader.

Kim NH, Delcroix M, Jais X, et al. Chronic thromboembolic pulmonary hypertension. *Eur Respir J*. 2019;53:1801915.

This review is the latest available summary of the 6th World Symposium on Pulmonary Hypertension as it relates to CTEPH. The manuscript provides a concise summary of the latest literature on CTEPH at the time of the symposium and provides the link between acute pulmonary embolism and CTEPH. It also provides an update on the diagnostic and treatment algorithm for CTEPH.

Konstantinides SV, Meyer G, Becattini C, et al. 2019 ESC guidelines for the diagnosis and management of acute pulmonary embolism developed in collaboration with the European Respiratory Society (ERS). *Eur Heart J*. 2020;41:543-603.

This important guideline is from the European Society of Cardiology in collaboration with the European Respiratory Society. The guidelines form the basis for diagnosis of acute pulmonary embolism and further provide a comprehensive management strategy for this disease. Many other international societies rely heavily on these specific guidelines by these two European societies.

  Summary

INTRODUCTION

The field of cardiac surgery has witnessed a significant transformation with the advent of percutaneous heart procedures. This chapter offers an exploration of these advancements, focusing on transcatheter interventions for valvular heart disease and hybrid approaches for atrial fibrillation (AF) ablation. It aims to provide an insightful narrative that intertwines historical evolution, technologic progress, and clinical outcomes.

At the forefront of this revolution is transcatheter aortic valve replacement (TAVR). Originally a novel alternative for high-risk patients, TAVR has evolved—as underscored by studies like Placement of Aortic Transcatheter Valves 2A (PARTNER 2A) and Surgical Replacement and Transcatheter Aortic Valve Implantation (SURTAVI)—into a widely accepted procedure across diverse patient groups. Similarly, transcatheter options for mitral valve pathology, such as transcatheter edge-to-edge repair (TEER) and valve-in-valve (ViV) placement, began to emerge as viable options for nonsurgical candidates and were soon after incorporated into contemporary guidelines as a result of seminal trials like Mitral Regurgitation–Functional (MITRA-FR) and Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy (COAPT).

More recently, similar advancements have been attempted in the field of tricuspid valve pathology, acknowledging their critical role in addressing a long-neglected cardiac condition. With promising results from early clinical trials such as TRILUMINATE, percutaneous intervention has slowly been growing but remains largely exploratory at this stage.

Similarly, advancements in AF ablation, particularly the hybrid approach that combines surgical and catheter-based techniques, have also been increasingly used. The efficacy of these integrated strategies has become increasingly accepted as a viable management strategy, especially for heart failure patients.

In summary, this chapter offers a comprehensive overview of percutaneous heart procedures, placing technical and procedural advances within the context of evolving cardiac care. It emphasizes the shift toward personalized, patient-centric treatment approaches, reflecting the ongoing innovation and multidisciplinary collaboration that define contemporary cardiac surgery and interventional cardiology.

TRANSCATHETER AORTIC VALVE REPLACEMENT

Introduction

After the first-in-human TAVR in 2002 and the first FDA approval in 2011, the field of aortic surgery has evolved considerably with TAVR. Subsequent approval in high-risk, then intermediate-risk, and, most recently, low-risk patients has led to a steady increase in TAVR procedures nationwide. Recent randomized clinical trials of TAVR in low-risk aortic stenosis (AS) patients with both balloon-expandable[1] and self-expanding[2] valves demonstrated that TAVR has noninferior or better clinical outcomes compared with surgical aortic valve replacement (SAVR) at 1 year. It should be noted that in both trials, the average age was 73 and 74, and all had transfemoral access. The outcome of TAVR in low-risk patients much younger than that remains unknown.

Clinical outcomes in TAVR have steadily improved annually since 2012. The latest analysis from the Society of Thoracic Surgeons (STS) and American College of Cardiology Transcatheter Valve Therapy Registry (TVT) provided current outcomes: a 30-day mortality rate of 2.6%, stroke rate of 2.3%, and pacemaker need of 10.8%.[3] This analysis included all patient risk profiles and all FDA-approved valve devices and should serve as an expectation and benchmark when providing TAVR.

Although over 95% of TAVR procedures in the United States are performed transfemorally, innovation in alternative aortic access for TAVR has improved clinical outcomes for those with prohibitive iliofemoral access. After suboptimal outcomes, the transapical and transaortic access used in the high-risk trials has decreased in use to <1% of TAVRs in the United States. (Transapical exposure is presented later in the “Mitral Valve” section.) Transaxillary, transcarotid, and transcaval represent the most common and successful approaches to alternative access and comprise approximately 4% of TAVRs performed in the United States.

Broader indications, such as bioprosthetic aortic valve degeneration, bicuspid aortic valve disease (BAV), and aortic insufficiency (AI), continue to increase the utility of TAVR. Although treatment of failed bioprosthetic valves was approved in 2015, the treatment of BAV and pure AI remains an off-label use of TAVR. Adjunctive techniques, such as aortic leaflet incision to avoid coronary obstruction and bioprosthetic valve ring fracture, have evolved to allow TAVR in many patients who were previously not considered candidates.

Currently, there are over 70,000 TAVRs performed in the United States each year. In 2016, TAVR procedural volume surpassed that of isolated SAVR in the United States, demonstrating the impact of new technologies and approaches.[3] Isolated SAVR volume remained steady until significantly decreasing in 2019 and is estimated at 30,000 cases per year in the United States. Like many procedures in cardiac surgery, TAVR has a significant connection between procedural volume and clinical outcomes among TAVR centers and operators.[4] In 2023, the US Centers for Medicare and Medicaid Services mandated that a TAVR center must perform a minimum of 20 procedures per year. Additionally, it is required that both a cardiac surgeon and interventional cardiologist evaluate the patient and perform TAVR together. The future direction of these criteria remains unknown. Here, we present the indications, preoperative evaluation, procedural steps, and medical management of TAVR.

Indications and Current Practice Guidelines

Evolution in TAVR has led to changes in both the US and European clinical practice guidelines. In 2020, the American College of Cardiology and the American Heart Association updated their recommendations,[5] and the European Society of Cardiology and European Association on Cardio-Thoracic Surgery followed in 2021.[6]

Severe AS is uniformly defined by the following echocardiographic criteria:

- Peak aortic jet velocity >4 m/s
- Mean aortic valve gradient >40 mm Hg
- Aortic valve area <1.0 cm^2

Among patients with an ejection fraction (EF) <50%, a dobutamine stress echocardiogram demonstrating an increase in stroke volume (SV) >20% and an elevation of mean gradient to >40 mm Hg and/or aortic valve area <1 cm^2 defines low-flow, low-gradient AS. Additionally, critical AS is defined as peak aortic jet velocity >5 cm^2 and mean gradient >60 mm Hg.

Aortic valve replacement (TAVR or SAVR) has a class 1 indication if severe AS has the following characteristics:

- Symptomatic in history or exercise test
- Accompanied by an EF <50%
- Low-flow, low-gradient AS (with SV reserve)
- Patient also undergoing other cardiac surgery
- Critical AS regardless of symptoms

Aortic valve replacement (TAVR or SAVR) has a class 2 indication if the following characteristics are present:

- Moderate AS during other cardiac surgery
- An annual progression of peak aortic velocity of >0.3 m/s/y
- An annual threefold increase in brain natriuretic peptide (BNP) versus age- and sex-based normal values
- Decrease in blood pressure on exercise test

Aortic valve replacement (TAVR or SAVR) is contraindicated in the following patients:

- Severe comorbidities with expected survival <1 year

TAVR-specific recommendations in the US guidelines include the following:

1. For AS with indication for aortic valve replacement (AVR), age 65 to 80, with no contraindication to transfemoral TAVR, either SAVR or TAVR is recommended.
2. For AS with indication for AVR, over 80 years old or with a life expectancy <10 years, and no contraindication to transfemoral TAVR, TAVR is recommended.
3. For AS with indication for AVR but valve or vascular anatomy is not suitable for transfemoral TAVR, SAVR is recommended.

TAVR-specific recommendations in the European guidelines include the following:

1. For AS with an indication for AVR, age over 75 years, high risk (STS Predicted Risk of Mortality [PROM]/EuroSCORE II >8%), or unsuitable for surgery, TAVR is recommended.
2. For AS with an indication for AVR, alternative access should be considered in inoperable patients unsuitable for transfemoral TAVR.

Fig. 115.1 summarizes the only class 1 indications in both practice guidelines when deciding on SAVR versus TAVR.[7]

Preoperative Evaluation and Valve Sizing

The decision to offer TAVR or SAVR to a patient with aortic valve disease is made by a heart team and considers many factors. The median age of patients undergoing TAVR in the United States is 80 years old.[3] Clinical evaluations that can aid in the TAVR versus SAVR decision-making include medical history, other organ system function, and frailty. Particularly important aspects of a patient’s history include ability to recover from sternotomy and cardiopulmonary bypass, any previous chest radiation, coronary artery disease, peripheral vascular disease, arrhythmia, and aortic disease. Concomitant coronary disease, aortic aneurysm, or any other indicated cardiac surgery clearly steers the patient toward SAVR. Reduced systolic ventricular function may not recover from SAVR well and lends toward TAVR. A history of heart block or preexisting pacemaker will not only influence the decision of SAVR or TAVR but will also be important in predicting arrhythmia after TAVR. ECG findings,

including QRS >120 ms, any degree of atrioventricular (AV) block, and any fascicular block, portend an increased risk of pacemaker requirement postoperatively. The superior outcomes of transfemoral TAVR compared with alternative-access approaches should weigh heavily in the decision regarding TAVR or SAVR. Additionally, patients with extensive peripheral vascular disease will have an increased risk of vascular complications despite adequate iliofemoral vessel size. Renal dysfunction requiring new-onset dialysis after TAVR is exceedingly low at $<0.5\%$, possibly favoring TAVR in advanced chronic kidney disease. History of stroke increases periprocedural stroke risk with both TAVR and SAVR, but recent data suggest the risk is less with TAVR. In either procedure, the history of stroke may lend toward the use of an embolic protection device. In addition to comorbidities, patient frailty should be weighed heavily when deciding on TAVR versus SAVR. Frailty is generally scored out of a total using a series of quantifiable tasks, including gait speed, grip strength, number of activities of daily living (ADLs) that the patient can complete, and serum albumin (Table 115.1).

TAVR success is highly dependent on the skilled interpretation of preoperative imaging and valve sizing. Preoperative CT imaging should be ECG gated, with IV contrast and <1-mm slices. Qualitative preoperative computed tomography angiography (CTA) analysis should include examination of valve shape and calcifications, other heart structures and coronary arteries, the aorta, and iliofemoral vessels. The left ventricular outflow tract should be examined for any heavy calcification, which is a risk for annular rupture, and any significant septal hypertrophy, which can cause a misdiagnosis and increases the risk of valve embolization during TAVR (Fig. 115.2). Calcification position and membranous septum length can help predict need for pacemaker after TAVR. Significant mitral annular calcification (MAC) is also a risk for surgical complications. Sites of subclinical aortic aneurysm and any significant aortic arch calcium should be noticed. A heavily calcified ascending aorta or porcelain aorta may preclude SAVR. The quality and technique of CTA for TAVR allow a comprehensive analysis of any coronary artery disease.

Quantitative measurements obtained before all TAVRs are as follows (Fig. 115.3):

- Aortic annulus area
- Aortic annulus perimeter
- Aortic root dimensions, each sinus
- Sinotubular junction height
- Coronary artery heights

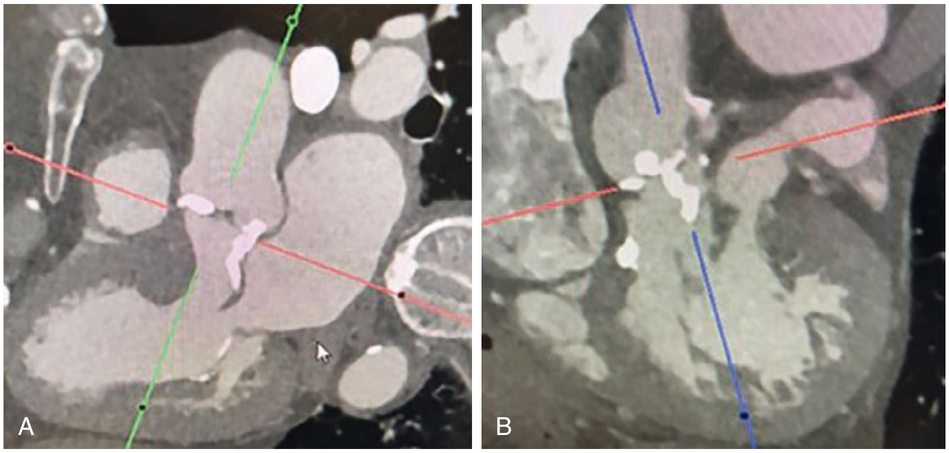

FIGURE 115.2 (A–B) Heavy left ventricular outflow tract calcifications.

- Deployment angles
- Iliac and femoral artery diameters

Generally, balloon-expandable valves are sized according to aortic annulus area, whereas self-expanding valves are sized based on aortic valve diameter. Valve manufacturers will provide a degree of oversizing for each valve size for a given annular or perimeter measurement.

Prevention of coronary obstruction generally requires a coronary height >10 mm and aortic sinus around that coronary of >30 mm. The risk significantly increases when both short coronaries are accompanied by an effaced sinus. Self-expanding valves have a sinotubular junction height requirement. The vascular access size for TAVR is 14 to 16 Fr and requires arteries >5 to 5.5 mm.

Valve Devices Available in the United States

Currently, for native valve TAVR, 72% of procedures are done with balloon-expanding valves, and 26.7% are done with self-expanding valves.[3] Device materials, specifications, advantages, and disadvantages are discussed in the following subsections. TAVR valves by any other manufacturer are currently investigational or have approval withdrawn.

Balloon Expandable

The SAPIEN 3 and SAPIEN 3 Ultra represent the third generation of TAVR valves manufactured by Edwards Lifesciences (Irvine, CA) (Fig. 115.4). The valve consists of a cobalt chromic frame, bovine pericardial tissue, and an outer textured polyethylene terephthalate sealing skirt. The stent frame is short, and the valve is intraannular. Improvements made throughout the course of development include lower access profile, addition and extension of the sealing skirt, and addition of a proprietary tissue fixation to prevent structural valve deterioration (Resilia). The SAPIEN 3 Ultra uses the Commander delivery system and eSheath+, both also from Edwards Lifesciences. The Commander delivery system is unique in its ability to be flexed 180 degrees, allowing for a smooth, atraumatic course around the aortic arch and cross the valve. The eSheath+ is hydrophilic and expandable, temporarily increasing by 2 Fr sizes as the valve passes through it in the iliofemoral vessels.

Self-Expanding

The EvolutPRO+ and EvolutFX represent the latest generation of TAVR valve manufactured by Medtronic (Minneapolis, MN) (Fig. 115.5). The valve consists of a nitinol frame, porcine pericardial tissue, and an external wrap of sealing tissue on the ventricular

side of the valve. The stent frame is longer, with a supraannular valve position. Improvements made throughout the course of development include recapturability, increased flexibility in the delivery system, and the addition of radiopaque markers to allow commissural alignment. The delivery system allows two-thirds deployment and assessment with the potential to recapture the valve as well as an in-line sheath for smaller vascular access.

Advantages of the SAPIEN system include lower rates of perivalvular leak (PVL) and pacemaker requirement. Advantages of the Evolut system include its recapturability, atraumatic deployment, and lower post-TAVR gradients because of its supraannular position. Further considerations regarding valve choice are listed in Table 115.2.

Procedural Considerations and Steps

Anesthesia Considerations

The determinants of anesthetic approach are most often the patient's comorbidities and method of aortic access. In 2019, 64% of TAVRs were done under conscious sedation. Data suggest improved outcomes when general anesthesia can be avoided.[8]

Transfemoral Access

Rarely, femoral artery calcification will require a surgical cutdown approach. The majority of TAVR procedures begin with three percutaneous vascular access sites: a large-bore femoral artery site for valve delivery, a 7-Fr femoral venous access size for placement of a temporary pacing catheter, and additional 5- to 6-Fr arterial access site for an angiographic imaging catheter that can be placed in the femoral or radial artery. The valve arterial access is preclosed with two Perclose (Abbott Cardiovascular Plymouth, MN) sutures (Fig. 115.6). Two sutures are placed at 10 o'clock and 2 o'clock (the anterior-posterior direction at 12 o'clock). The closure device consists of a footplate that is opened and opposed to the inner arterial wall. The sutures are then deployed and secured. Lastly, the footplate is closed, and the device is removed over the wire. A 9-Fr sheath then nicely plugs the access dilated by the Perclose sutures.

Heparinization, with an activated clotting time (ACT) goal of over 250 seconds, should be achieved before placing large-bore access to reduce vascular complications. Here, the procedural steps differ slightly depending on the valve type used. For balloon-expandable valves, the large-bore sheath is placed before crossing the aortic valve. For self-expanding valves, the sheath or device is introduced after crossing the aortic valve. After dilating the femoral artery, the sheath or device should be advanced over a stiff wire under fluoroscopic guidance.

Pacing

After or during vascular access, a transvenous pacemaker can be advanced from the femoral vein (usually on the nondevice side) to the right ventricle (RV). The pacemaker should be tested and secured to prevent loss of capture during TAVR. The temporary pacemaker should again be tested immediately before TAVR deployment. Loss of capture can result in device malpositioning or embolization. A typical rate of pacing to allow a temporary decrease in cardiac output and blood pressure and facilitate balloon-expandable TAVR is 180 beats/minute. Pacing for self-expanding valve deployment is generally 120 beats/minute but is less critical, and it is skipped altogether if the patient does not tolerate pacing.

Cerebral Protection

Currently, the Sentinel embolic protection device (Boston Scientific, Marlborough, MA) is used in approximately 15% of TAVRs. The only large, randomized clinical trial on the use of cerebral protection (PROTECTED TAVR) demonstrated no significant difference between the rates of stroke within 72 hours or before discharge when cerebral protection techniques were used. A nonpowered trend suggests disabling stroke specifically may be lower with Sentinel device use (0.5 vs. 1.3%).[9] Embolic protection is a reasonable addition to those at increased risk for disabling stroke. It requires right radial artery access and the absence of atherosclerotic disease in the proximal head vessels or aortic arch, and it should be placed after anticoagulation.

Angiography

A pigtail-shaped angiographic catheter is then advanced to the aortic root. The typical contrast dose is 20 cc given at a rate of 10 cc/second. This may vary based on the patient's renal function and size. This aortogram will demonstrate anatomy and deployment angle. It is critical to find the coplanar angle at which the nadirs of all three sinuses of the aortic root are in the same plane (Fig. 115.7). Self-expanding valves also use a cusp-overlap view for precise TAVR implantation depth in the noncoronary sinus.

Valve Crossing and Stiff Wire Placement

When vascular access, pacing, and angiography are set up, the stenotic aortic valve needs to be crossed. This is most often achieved with an AL-1 catheter and a straight, stiff, hydrophilic glidewire. Positioning the end of the catheter at the level of sinotubular junction and aiming for any gaps in the calcium works best. If one position is unsuccessful after multiple attempts, minute changes in catheter rotation or depth should be made. If multiple catheter positions and attempts are unsuccessful, an AL-2 catheter is the next best choice. Additionally, attention should be given to the timing of attempts, which need to be in systole, especially in bradycardic patients.

After crossing the aortic valve, a pre-TAVR aortic valve gradient is obtained, and a stiff wire is carefully placed in the left ventricular apex. This will often require a catheter change from the AL-1 to a pigtail-shaped catheter to get a smooth, atraumatic positioning of the stiff wire. Common wires used, listed in increasing stiffness, are the Safari (Boston Scientific, Marlborough, MA), Amplatz extra stiff (Cook Bloomington, IN), Confida (Medtronic, Minneapolis, MN), Amplatz super stiff (Boston Scientific, Marlborough, MA), and double-curved Lunderquist (Cook Bloomington, IN). The Amplatz wires will require shaping of the flexible tip into a broad curve. It is best practice to maintain visualization of the stiff wire in the ventricle throughout the procedure to avoid ventricular injury or wire loss.

Pre- Versus Post-Balloon Valvuloplasty

The decision to pre- or postdilate via balloon valvuloplasty is based on anatomic factors and varies widely in practice. The inability to pass a TAVR device through the aortic valve is an obvious need for predilation. Therefore, predilation should be considered in especially tight valves (<0.75 cm^2) or high mean gradients (>60 mm Hg). Even if the valve can be passed through the annulus, the occlusion of an already critically stenosed aortic valve can make the patient hemodynamically unstable, leading to a rushed or inaccurate deployment. Although the correlation is not proven, every ballooning of the aortic valve annulus carries the potential for debris or calcium embolization and stroke. Therefore, risks of stroke and intraoperative instability need to be weighed carefully. Pre-TAVR balloon valvuloplasty is universally employed by most operators in treating BAV to create a more round, less elliptical area for TAVR.

Noncompliant balloons and rapid ventricular pacing are used for balloon valvuloplasty. The Z-Med (B Braun, Bethlehem, PA)

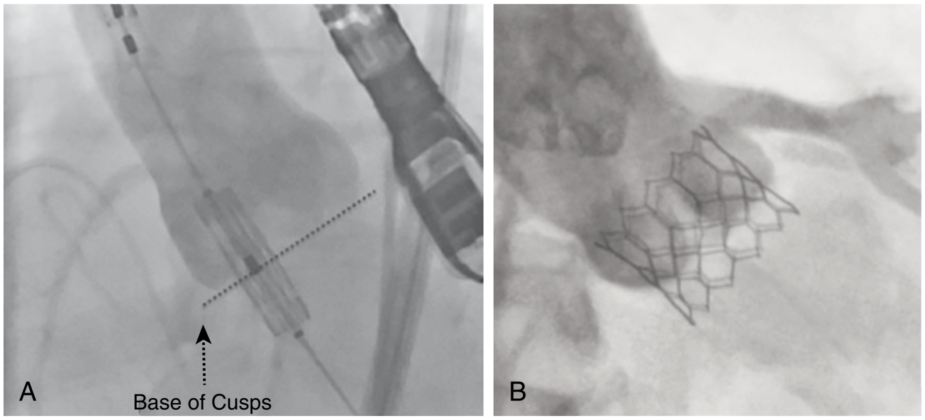

FIGURE 115.7 (A) Coplanar angle and SAPIEN 3 positioning. (B) Transcatheter aortic valve replacement, 80%/20% placement.

and TrueDilation balloon (Bard, Tempe, AZ) are the most commonly used balloons. For pre-TAVR valvuloplasty, balloon sizing should be just big enough to get the device through the aortic valve in a safe and stable manner, ≤20 mm. Do not perform pre-TAVR balloon valvuloplasty unless your TAVR valve is open and ready for use. Acute AI is a known complication of balloon valvuloplasty, can quickly lead to hemodynamic instability, and is only treated with subsequent TAVR. Post-TAVR balloon valvuloplasty is necessary when post-TAVR aortogram or echo shows significant (≥ moderate) perivalvular AI or there is a significant (>15- to 20-mm Hg) remaining post-TAVR mean gradient. When using a balloon-expandable valve, the most efficient approach to post-TAVR dilation is to use the deployment balloon in the delivery system with an additional 1 to 2 cc of contrast added. Post-TAVR dilation for a self-expanding valve requires a Z-Med or a TrueDilation balloon and is usually 1:1 sized or 1- to 2-mm undersized. Post-TAVR balloon valvuloplasty carries a risk of device embolization and should be avoided with a valve positioned high in the annulus. Postdeployment significant intravalvular regurgitation is very rare and best treated with immediate ViV TAVR.

Balloon-Expandable Deployment

With either valve type, collaboration with industry representatives is critical for trainees to fully understand all working parts of transcatheter valve devices. For deployment of the SAPIEN 3 (Edwards Lifesciences), balloon-expandable valve, the 14- or 16-Fr Edwards eSheath is placed over a stiff wire when obtaining vascular access. With the Commander delivery system (Edwards Lifesciences), the valve and deployment balloon are introduced in parallel. The balloon is withdrawn into the valve before crossing the aortic arch or valve, its position within the valve is fine-tuned, and the delivery system is locked. Here, an additional unlock and lock can remove any tension built up in the system. As the delivery system is advanced across the aortic arch, a flex knob is turned to articulate the distal end of the catheter into a candy-cane shape that nicely traverses the arch and valve atraumatically. The TAVR is advanced across the valve while monitoring for hemodynamic stability. The part of the delivery system that pushes the valve through the sheath is then pulled back. The ventricular end of the large, middle marker is lined up with the coplanar line at which the nadirs of all three cusps align. It can be important to remember that this marker is on the balloon and not the valve. If, by chance, the valve is not centered on the balloon, this large marker will need to be positioned differently.

At this point, a second time-out can be useful to get the undivided attention of the key participants. These next steps should take approximately 5 seconds:

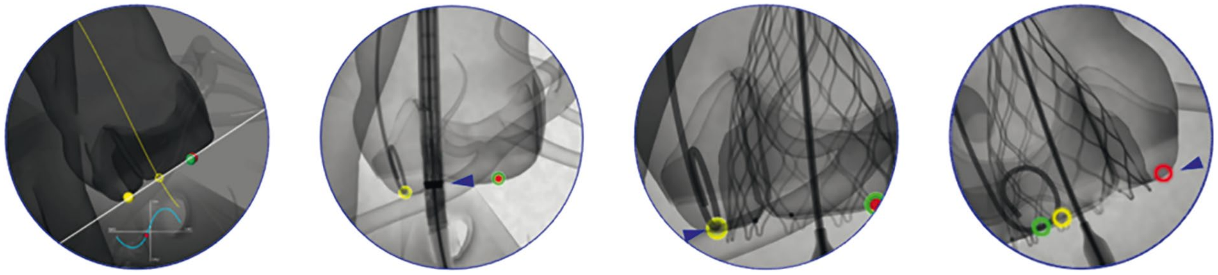
- Rapid pacing on, with confirmation of pacing capture
- Visualize decrease in cardiac output and blood pressure on arterial line
- Aortogram
- Inflate balloon at medium speed, allowing the positioner to make fine adjustments in position
- Verbally confirm both operators agree with implantation depth
- Inflate the rest of the balloon rapidly
- Visually confirm syringe is completely expelled, and deflate the balloon rapidly
- Rapid pacing off

The general goal implantation depth is 80% of the valve above the annulus and 20% below (see Fig. 115.7). As the implantation depth rises more aortic in direction, the risk of pacemaker requirement goes down, but the risks of PVL and valve embolization go up. The SAPIEN 3 valve generally foreshortens from the ventricular side up. Efficient, clear communication between team members, positioner and deployer, is critical to precise valve positioning.

Self-Expanding Deployment

There is a slight difference in the order of procedural steps when performing TAVR with a self-expanding valve because of the presence of an in-line sheath with the Evolut system (Medtronic). Unlike in balloon-expandable TAVR, the aortic valve is crossed before the vascular access is dilated. The order of steps is generally as follows: vascular access, cross valve, dilate vascular access, and introduce the delivery system. The valve is always inspected under fluoroscopy to ensure tethering paddles are in the proper location before being inserted. Once introduced, with the flush port in the 3 o'clock position, there is no further prep of the device needed, and the valve can be advanced across the aortic arch and valve.

In an effort to minimize conduction disturbance, the Evolut system (Medtronic) uses two views in deployment: the traditional coplanar view and a left-right cusp-overlap view. The cusp-overlap view better demonstrates TAVR depth in the noncoronary sinus (Fig. 115.8). The ideal implantation depth is 3 to 5 mm below the annulus. On the EvolutFX, there are radiopaque markers at



Determine cusp overlap imaging projection through precise CT planning.

Reduce interaction with conduction system; start deployment with marker band near bottom of pigtail and approach target depth from above.

Assess depth accurately at the NCC in cusp overlap view.

Confirm depth at the LCC using an LAO view.

FIGURE 115.8 Cusp-overlap technique for Evolute (Medtronic, Minneapolis, MN) placement. *LAO,* Left anterior oblique; *LCC,* left coronary cusp; *NCC,* noncoronary cusp.

3-mm depth. Because the valve dives in slightly with deployment, start deployment with the marker band of the deployment system on the coplanar line, which is also the maximum depth of the pigtail catheter. The deployment can be divided into thirds. The first and last third are very slow, whereas the middle third is faster.

1. Initially in the cusp-overlap view, the valve is deployed very slowly, starting with the marker band at the annulus and ending with it at the third stent frame or "node." The 3-mm radiopaque markers should be aligned as closely as possible to the nadir of the pigtail.
2. The middle one-third of deployment is more rapid because cardiac output is obstructed by the valve. Pacing at 120 beats/minute is helpful but not necessary. The marker band is withdrawn past the stent but not past the tethering paddles. There will be a "rumble strip" or bumpy feel to the delivery system immediately before this point of no recapturability.
3. Between the second and last thirds of deployment, the depth is confirmed on aortogram in both the cusp-overlap and coplanar view. Assessment of conduction and PVL can also be made at this point. If the position is unsatisfactory (1 mm or >5 mm), the valve can be recaptured by simply rotating in the opposite direction. It can be partially or fully recaptured but should not be repositioned within the middle one-third of the valve.
4. For deployment of the final third of the valve, the wire is retracted a few millimeters to relieve tension in the system, gentle forward pressure is placed on the delivery system, and deployment is very slow until both tethering paddles are released. Finally, the system is withdrawn into the descending aorta and recaptured before removal.

Assessment

Immediate assessment of cardiac rhythm is critical. Temporary retention of the pacing catheter during post-TAVR observation lead should be considered for those with new conduction disturbances (left bundle branch block [LBBB], PR/QRS >20 ms), transient or sustained heart block, or high preexisting risk for conduction disturbance (right bundle branch block [RBBB]). Aortogram immediately after deployment is critical to evaluate any AI, coronary obstruction, the depth of TAVR implantation, the integrity of the ascending aorta and aortic annulus, and any contrast in the pericardium. It is recommended that a transthoracic echo be done in the procedure room or shortly thereafter in recovery. Again, the echo is looking for the same complications as the aortogram, with the addition of any changes in ventricular function or mitral valve function. Although same-day discharge has been reported after TAVR, the majority of practitioners observe cardiac rhythm for 24 hours and repeat the transthoracic echo before discharge.

Alternative Access

In 2019, over 95% of TAVRs were done transfemorally.[3] Transfemoral access has repeatedly demonstrated superior outcomes to alternative-access TAVR. Transaortic and transapical approaches used in the high-risk and inoperable clinical trials demonstrated worse outcomes than SAVR.[10] The three most common alternative-access sites are transcarotid, transaxillary, and transcaval. More recently, iliofemoral intervention immediately before TAVR has substantially increased in an effort to maintain the benefits of transfemoral access. Improved outcomes, including early and late survival, are seen with transfemoral TAVR with concomitant peripheral intervention over nontransfemoral TAVR.[11] Peripheral intervention, either immediately before or after, accompanies 4% to 6% of all transfemoral TAVR. Technical options include balloon angioplasty or stenting, drug-coated balloon therapy, and intravascular lithotripsy.

The most contemporary data suggest both transcarotid and transaxillary approaches have similar early safety data to transfemoral TAVR.[12,13] Data are conflicting as to whether transaxillary or transcarotid access carries a higher risk of stroke. Long-term survival is generally reported lower in alternative-access TAVR, likely because of comorbidity correlated with peripheral vascular disease.

When evaluating anatomy for transcarotid and transaxillary access, vessel size, calcification, and tortuosity criteria are similar to those for transfemoral access. For balloon-expandable valves, a healthy vessel over 5.5 mm is required. For self-expanding, 5.0-mm access is required. These size criteria increase if the access vessel is calcified. Circumferential calcium is a significant predictor of vascular access complications and should be pretreated or avoided. Although carotid and axillary vessels are generally smaller than femoral arteries, they are less likely to be calcified, providing good sites for alternative access for TAVR.

Transaxillary

Transaxillary or transsubclavian access is the most common alternative-access site. Access can be performed percutaneously; however, the risk of vascular complication is higher. Manual pressure application in this area can be difficult, and a lateral, open approach is recommended. The axillary artery is exposed via a subclavicular incision in the deltopectoral groove. The pectoralis muscles can be separated or divided and the axillary vein retracted inferiorly to expose the artery. The brachial plexus should be identified and avoided. Next, after proximal and distal control of the artery, purse-string suture (5.0) is then placed and snared. Needle access is generally made more laterally, through the skin and to maintain a shallow angle of approach (Fig. 115.9). The access is then serially dilated over a stiff wire, and the large-bore sheath is advanced to the ascending aorta. After TAVR, the sheath is removed, the axillary artery is controlled proximally and distally,

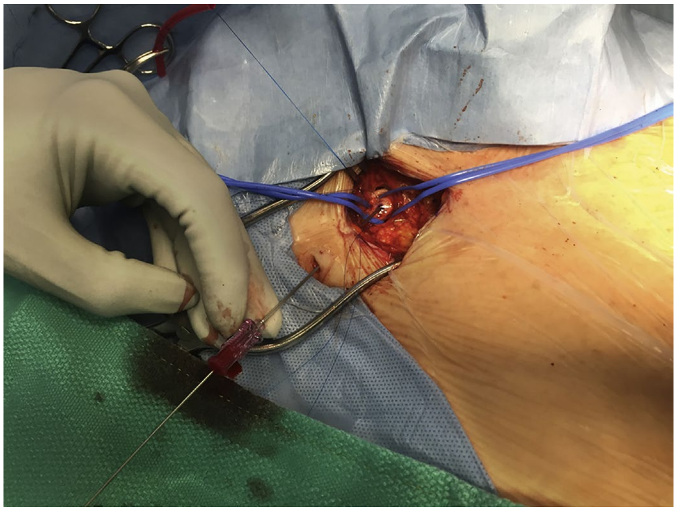


FIGURE 115.9 Transaxillary exposure for transcatheter aortic valve replacement. (From Kindzelski B, Mick SL, Krishnaswamy A, et al. Evolution of alternative-access transcatheter aortic valve replacement. *Ann Thorac Surg*. 2021;112[6]:1877-1885.)

and the artery is primarily repaired. Simply, tying the purse-string suture may lead to narrowing of the access. As with transfemoral access, a completion angiogram of the access site is helpful to avoid delayed complications. Alternatively, an 8-mm or larger conduit can be sewn onto the axillary artery and stretched out laterally to provide access. This sometimes allows a smoother angle of approach to the artery. Transaxillary access should not be used in the setting of an ipsilateral, patent mammary graft or dialysis access fistula.

Transcarotid

CTA neck and carotid duplex should be used to evaluate carotid size and health. Positioning the neck in extension with the patient looking to the opposite side is best. Transcarotid aortic access begins with an incision on the medial edge of the sternocleidomastoid in the lower half of the neck. After retracting the muscle, the carotid sheath can be entered, and the common carotid artery can be isolated. Avoiding electrocautery while within the carotid sheath may prevent vagus nerve injury. The internal jugular vein is retracted laterally, and the vagus nerve is identified and avoided. Clamping the distal carotid artery during the procedures is essential because it provides cerebral protection. The mean arterial blood pressure should be higher when the carotid artery is clamped, >80 mm Hg. Again, although a purse-string suture may help with hemostasis during the procedure, it should not be used for closure because it will stenose the carotid. Primary repair of the arteriotomy is best. Before closure, the proper sequence of flushing the arteriotomy is imperative to flush out any debris or potential emboli from the artery. First, the artery should be flushed with saline while clamped, and then the distal clamp is removed to allow back-bleeding into the surgical field (Fig. 115.10).[14]

Transcaval

First developed in 2013, transcaval access involves large-bore femoral venous access and puncture out of the inferior vena cava (IVC) through the retroperitoneal (RP) space and into the infrarenal aorta. After completion of the TAVR, the hole in the infrarenal aorta is closed with a patent ductus arteriosus (PDA) occlude (off-label use). The inherent positive pressure of the unviolated retroperitoneum allows this approach to be safely performed and any aortic bleeding to be shunted into the IVC rather than bleeding freely into the RP space. Precaution should be used in those with prior surgery done via an RP approach. Advantages of a transcaval approach include the lack of an incision and therefore avoidance of general anesthesia and possibly lower stroke rate than transaxillary or transcarotid. Disadvantages include few bailout options for complications and the requirement of advanced endovascular skill set and equipment (Fig. 115.11).[15]

Preparing for Sheath Insertion

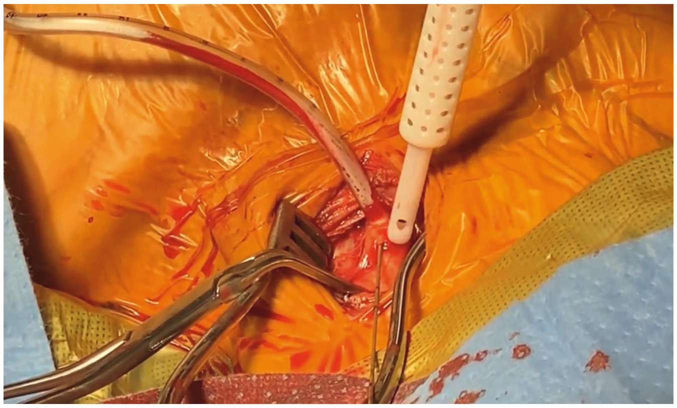

FIGURE 115.10 Transcarotid exposure for transcatheter aortic valve replacement. (From Allen KB, Watson D, Vora AN, et al. Transcarotid versus transaxillary access for transcatheter aortic valve replacement with a self-expanding valve: a propensity-matched analysis. *JTCVS Tech.* 2023;21:45-55.)

When evaluating anatomy for possible transcaval approach, a clear window of healthy infrarenal aorta, ≥10 mm, is required. A minimum of 2 cm between the renal arteries and access site is recommended. Evaluation of the RP space between the IVC and aorta should exclude bowel or any blood vessels; however, the exact distance between the two structures is less important. Although transcaval access allows TAVR in those with significant peripheral vascular disease, 8- to 10-Fr femoral artery access is needed for snare and balloon access to the aorta. If a possible bailout stent graft is being considered, this access need could increase in size. Lastly, the length from the IVC crossing site to the femoral vein needs to be 5 cm shorter than the large-bore sheath length.

Steps in transcaval access include the following:

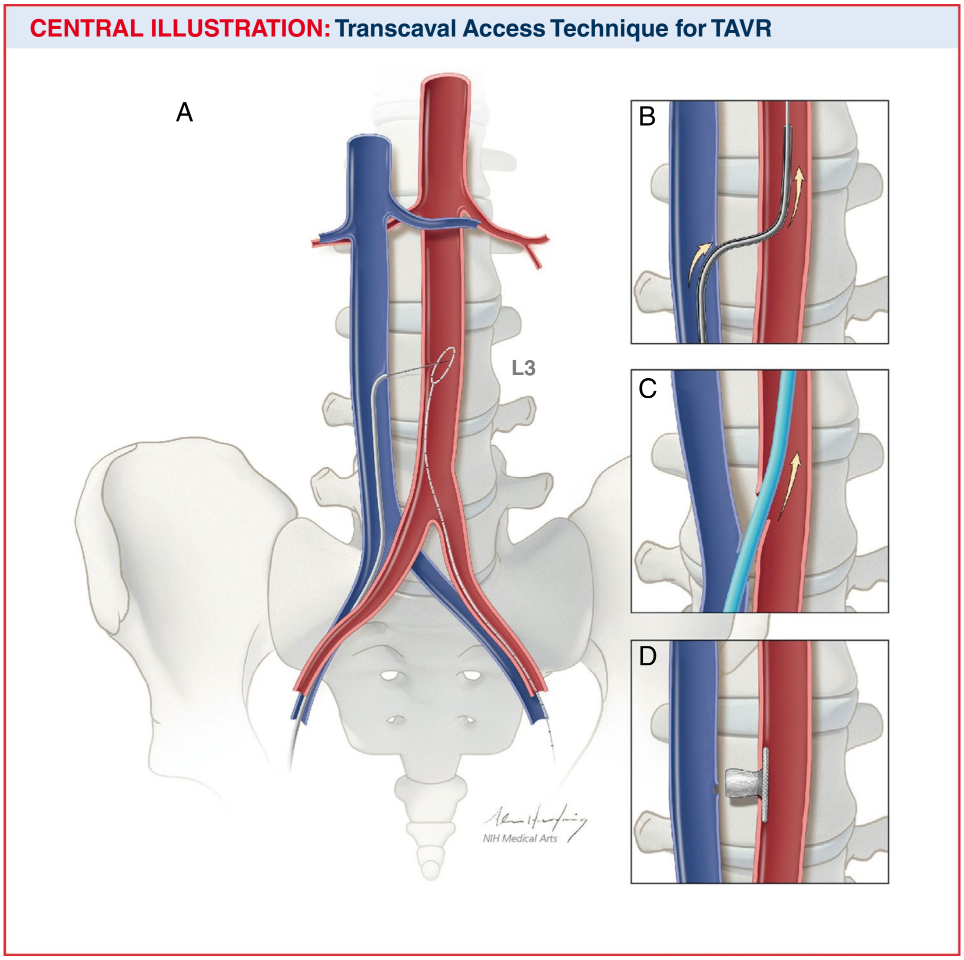
- 8-Fr femoral venous and femoral artery access and preclosure and anticoagulation
- Simultaneous venogram and aortogram to confirm crossing angle
- Positioning of an Amplatz Gooseneck snare (Medtronic) in the infrarenal aorta
- Positioning of an internal mammary (IM) guide catheter, microcatheter (NaviCross, Terumo, Sunrise, FL), piggyback wire converter (Teleflex, Wayne, PA), and backward-loaded 0.14″ Astato wire (Asahi, Irvine, CA) in the IVC at the level of crossing, directed at the aortic snare
- Application of electrocautery to the wire (cutting at 50 W) and advancement across IVC into aortic snare. Biplane fluoroscopy is helpful.
- Snare the 0.14″ wire and advance to the aortic arch, followed by the microcatheter.
- Wire is exchanged for a stiff wire (Lunderquist), access is dilated, and a 14-Fr sheath is placed in descending aorta.

Steps in transcaval closure are as follows[16]:

- A steerable Agilis catheter and 0.32″ wire (Abbott, Chicago, IL) are placed within the large-bore TAVR sheath. At this point, another 0.14″ backup wire is introduced in parallel.
- An aortic balloon (Tyshak-II, B. Braun Interventional Systems Inc., Bethlehem, PA) is placed in the infrarenal aorta via femoral artery.
- Partially deploy a Amplatzer ductal occluder (ADO-1, size 10/8 if aortic access <18 Fr). Withdraw sheath all the way into IVC (RP bleeding will occur if sheath is in RP space). Withdraw Agilis to oppose Amplatzer to aortic wall.
- Inflate balloon for 5 minutes. Fully deploy the ductal occlude during this time.
- Aortogram, remove bailout wire, then reverse anticoagulation or continued balloon occlusion.

Transcatheter Aortic Valve Replacement in Bicuspid Aortic Valve Disease

After approval for use in low-risk patients, TAVR for BAV has increased in application. Although approved for all valve types,



CENTRAL ILLUSTRATION: **Transcaval Access Technique for TAVR**

FIGURE 115.11 (A–D) Transcaval access for transcatheter aortic valve replacement *(TAVR)*. (From Courtesy A. Hoofring, NIH Medical Arts Branch.)

it is notable that there were no bicuspid patients in any of the landmark TAVR clinical trials. Although early registry outcomes suggested increased stroke, annular rupture (balloon expanding), and severe PVL (self-expanding) with TAVR for BAV compared with tricuspid valves,[17] more contemporary results demonstrate acceptable outcomes. To date, there have been no randomized controlled trials of TAVR versus SAVR for BAV. The latest TVT registry results examining 3168 propensity-matched low-risk patients undergoing TAVR between 2015 and 2020 showed equal rate of mortality, stroke, procedural complications, and valve hemodynamics among patients with bicuspid and tricuspid aortic valve disease.[18] Additionally, bicuspid registries of select, anatomically favorable, low-risk patients show similar outcomes to low-risk tricuspid valve patients.[19] National registries and nonrandomized, prospective studies of TAVR for BAV are ongoing.

Particular challenges remain in TAVR for BAV, such as the increased elliptical shape of the BAV annulus and severe asymmetric calcification. When evaluating BAV patients for TAVR, close review of any associated aortopathy that requires or may require surgical repair in the future is necessary. Similarly, with SAVR, BAV patients undergoing TAVR have an increased need for pacemaker, which may influence valve choice. Sievers type of BAV correlates with outcomes in TAVR. Type 1, with fusion of two leaflets and a single raphe, is most common. The anatomy of valve calcium needs to be highly scrutinized. Often, type 1 BAV can have a heavily calcified raphe. This long, spear-shaped calcium can sit exactly perpendicular to the aortic valve annulus and carry an additional risk of annular rupture with balloon-expandable TAVR or an increased risk of PVL with self-expanding TAVR. Increased raphe and valve calcium have been shown to have increased complications, including 1 year mortality with TAVR. On the other hand, Sievers type 0 BAV, bicommissural with no raphe, carries a higher risk of increased transvalvular gradient and coronary obstruction after TAVR.[20] Without significant raphe calcium (>4 mm), balloon-expandable TAVR offers fewer complications than self-expanding in the setting of BAV.

When sizing for TAVR in BAV, annular sizing with nominal oversizing is generally best. However, it is prudent to look at both the annulus size and the valve orifice size at the level of the calcifications. If the valve orifice is much smaller than the annulus, a slightly higher positioning of the valve may offer a lower chance of valve underexpansion. A pre-TAVR balloon valvuloplasty with an undersized balloon is recommended to aid valve crossing and TAVR positioning and create a rounder anchoring area for TAVR. Because BAV often has denser calcium and TAVR for BAV often requires additional ballooning, cerebral protection is reasonable in BAV cases. The remaining technical aspects of TAVR for BAV are the same as for tricuspid disease.

Valve-in-Valve

ViV TAVR within a failed surgical bioprosthesis comprises 6.7% of current TAVRs. After FDA approval in 2015, ViV TAVR is now a 2a recommendation among symptomatic bioprosthetic AS or regurgitation in those at high risk for repeat surgery. There are many factors relevant in the decision of redo SAVR versus ViV TAVR, including patient age and risk, valve size, and risk for coronary obstruction. Although the risks for coronary obstruction and high residual gradients are higher with ViV TAVR, the risks of permanent pacemaker, PVL, and annular rupture are significantly lower. The PARTNER 2 trial included a nonrandomized ViV registry arm. Five-year results demonstrated acceptable valve-related outcomes among high-risk patients, with structural valve deterioration or failure at 7% and reintervention at 6%. The mean transvalvular gradient and quality of life remained statistically unchanged.[21] Self-expanding valves are more commonly used for ViV procedures because of their lower gradients; however, data are mixed regarding survival after ViV TAVR with balloon versus self-expanding valves. It is clear that ViV procedures in smaller valves (true internal diameter ≤21 mm) portend a lower late survival.[22] Although periprocedural morbidity and mortality are usually reported as lower or noninferior to ViV TAVR versus redo SAVR, long-term results and the best application of a ViV approach remain unclear.

Coronary obstruction occurs twice as often in ViV TAVR and is more often left sided. Risk is increased with effaced sinuses and externally mounted leaflets. Leaflet length should be directly compared with coronary height and sinus of Valsalva height. However, even with a seemingly adequate coronary height, a badly effaced sinus can significantly increase the risk. For anatomies at risk of coronary obstruction, a smaller size valve, lower placement, or surgical replacement should be considered. Coronary protection techniques include positioning a guide catheter and wire and, potentially, an angioplasty balloon or undeployed stent in the left anterior descending (LAD) artery, ± the left circumflex, before TAVR. The need for bailout coronary revascularization is associated with a high operative mortality. An adjuvant procedure, the bioprosthetic aortic scallop international laceration to prevent iatrogenic coronary obstruction (BASILICA) technique, involves puncturing through the base of the left leaflet, snaring the wire to create a loop through the leaflet. Then the wire is electrified with cautery and withdrawn to lacerate the leaflet.

Detailed specifications of the surgical bioprosthesis, such as true internal diameter, fracturability, leaflet mounting and length, and expected durability, are necessary for ViV TAVR planning. Additionally, echo, transesophageal, if necessary, should exclude endocarditis, PVLk, or other anatomy excluding a transcatheter approach. TAVR in stentless valves has been reported but is difficult because of the lack of radio-opaque markers and often heavy calcifications. Sizing for ViV TAVR is based on the true internal diameter of the surgical bioprosthesis. The ViV app (developed by Vinyak Bapat) can be helpful in sizing, detailing fluoroscopic appearance of specific ViVs, and specification of surgical valves. In sizing, it is important to remember that the size as referred to by manufacturers is not uniform and does not refer to the true internal diameter. For example, a size 26 in one type of valve can have a very different true internal diameter than a size 26 of another type of valve.[23] Additionally, crossing a bioprosthetic valve is generally more difficult than crossing a native valve. Pre-TAVR balloon valvuloplasty is usually reserved for inability to get the valve across, not necessarily just a wire. Goal implantation depth is similar to native valve TAVR, at 3 mm below the surgical valve ring in self-expanding valves and 80% aortic/20% ventricular for balloon-expanding valves. This may be adjusted if the risk for coronary obstruction is high. The remainder of the ViV procedure is similar to native valve TAVR and is often made easier by fluoroscopic markers.

High postprocedural gradients are significantly more common after ViV TAVR compared with native valve TAVR and are associated with decreased valve durability and increased long-term mortality. Risks for high gradient after ViV TAVR include starting with a small valve or preoperative patient-prosthesis mismatch and balloon-expanding TAVR compared with self-expanding. Although degeneration of small bioprosthetic valves traditionally could only be repaired adequately with redo surgery, bioprosthetic valve fracture has emerged as a helpful technique to lower gradients with ViV TAVR, particularly in small valves. The technique is performed after ViV TAVR if gradients remain high (>10 mm Hg) and involves overexpansion of the surgical valve until the point of ring fracture using a high-pressure, noncompliant balloon under rapid ventricular pacing. Generally, the balloon size is 1 mm larger than the labeled valve size of the surgical valve. When using a self-expanding valve, the size of the waist of the TAVR valve should be noted, and balloon size should not exceed >2 mm above the waist diameter. The most commonly used balloons are the TrueDilation and the Atlas Gold (Bard, Tempe, AZ). The best way to achieve high pressure in the limited time allowed by rapid pacing is to use a stopcock and the balloon inflation port and a combination of hand (first with a large syringe) and device inflation. Fracture and valve expansion can be recognized fluoroscopically or by a sudden decrease in inflation device pressure. After exhaustive ex vivo testing, the balloon size and atmospheres of pressure at which each surgical bioprosthetic will fracture are now available in the literature. It should be noted that Trifecta (Abbott) and Hancock (Medtronic) valves cannot be fractured. Balloon fracture of ViV TAVR can add 3 to 4 mm to the true internal diameter of the surgical valve and, on average, reduce the mean gradient from 17 to 8 mm Hg.[24]

Transcatheter Aortic Valve Replacement for Aortic Insufficiency

TAVR for AI without concomitant stenosis and calcification can be performed with off-label use of the SAPIEN 3 or with investigational devices, such as the Trilogy valve (JenaValve, Irvine, CA) and J valve (JC Medical, Burlingame, CA). Although TAVR for AI is increasing, it remains very rare, at <1% of all TAVR. The 2020 American Heart Association (AHA) valve guidelines only mention TAVR for AI in a recommendation against TAVR for operable patients with AI in favor of SAVR. When considering TAVR for AI, it is important to understand the mechanism of AI and exclude disease related to aortic root anatomy. TAVR for AI clearly carries higher periprocedural risks than TAVR for AS. The aortic regurgitation (AR) TAVR registry following outcomes of TAVR for AI demonstrates similar perioperative mortality between SAVR and TAVR for AI. Retrospective results suggest that TAVR for AI has a lower early mortality compared with SAVR but a higher long-term mortality.[25] It remains unclear if self-expanding or balloon-expandable TAVR is better for AI. Oversizing by 20% to 30% is recommended to avoid TAVR migration or embolization. Self-expanding may offer more area of contact or anchoring if the outflow cage of the Evolut (38-mm) contacts the aorta at the sinotubular junction.

Devices for AI have markers that allow commissural alignment and an anchoring mechanism that attaches to the outside of the leaflet, using the leaflet tissue itself for anchoring. The ALIGN-AR trial using the Jena valve has completed enrollment, and initial results are promising, with 30-day cardiovascular mortality at 1.4% and good hemodynamics but a high pacemaker requirement rate.

Medical Management

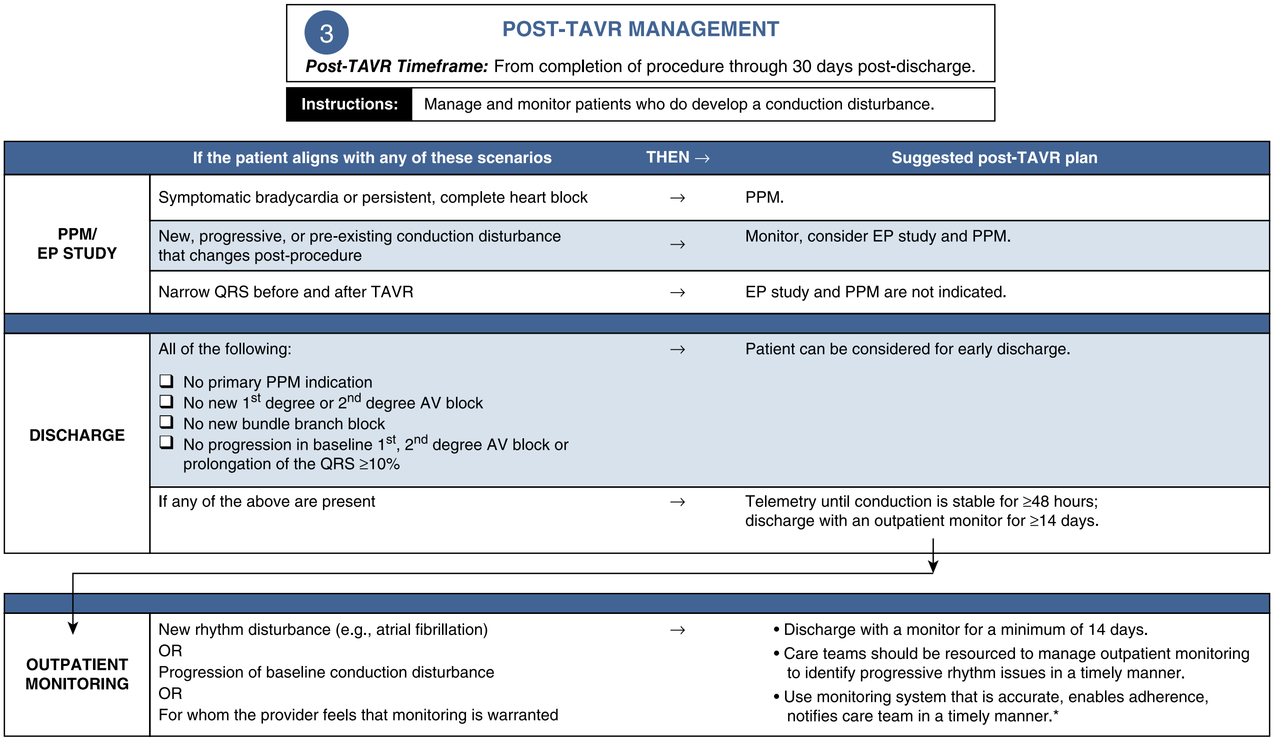
Average hospital stay after TAVR is 2 days. Next-day or same-day discharge is recommended only for those at lowest risk for heart block.[26] Common complications to monitor for are vascular injury and heart block. A repeat, predischarge echo is also recommended, too, not only look for complications (valve positioning, PVL, pericardial effusion) but also to serve as a new baseline for future comparison.

The majority of post-TAVR AV conduction delays happen in the first 48 hours after TAVR. However, it remains critical that those at risk for subsequent conduction disturbance be monitored longer with an outpatient ambulatory ECG monitor. LBBB is the most common conduction abnormality after TAVR. Risks include depth of implantation and self-expanding prosthesis. LBBB after TAVR can lead to heart failure and the later need for a permanent pacemaker (PPM). It remains unclear in the literature whether the placement of a PPM after TAVR decreases survival significantly in the long term.

Pacemaker placement after TAVR has steadily decreased since 2015 as a result of procedural insights. The adjusted goal of implantation depth from 20% to 10% in balloon-expandable TAVR and the cusp-overlap technique in self-expanding TAVR have helped significantly. In 2017, the number of outpatient post-TAVR patients requiring new pacemaker placement surpassed those of inpatients. In 2020, the American College of Cardiology summarized existing data and made recommendations, as shown in Fig. 115.12.[26]

Additional medical management considerations include antiplatelet therapy and monitoring. Similar to SAVR patients, an echocardiogram at 1 month and then annually to evaluate for structural valve deterioration is best practice. An early increase in transvalvular gradients after TAVR should prompt CTA to evaluate for leaflet thrombosis. Subclinical leaflet thrombosis seen on follow-up echo or CT is most often resolved with anticoagulation. Randomized clinical trials have demonstrated that neither prophylactic anticoagulation nor dual-antiplatelet therapy after TAVR significantly reduces the instances of leaflet thrombosis or structural valve deterioration; both do, however, increase bleeding events.[27,28] Therefore, unlike SAVR, guidelines recommend only lifelong aspirin after TAVR. Additionally, management guidelines recommend (2b) an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) in patients undergoing TAVR because it has been shown to reduce long-term mortality. Finally, similarly to heart valve replacement, endocarditis prophylaxis is recommended before dental work and any invasive procedures.

The evolution of transcatheter therapy for the aortic valve has been exponential and extraordinary. Data regarding extended results are now becoming available, with 91% of all TAVR patients being free from structural valve deterioration at 5 to 10 years.[29]



3 **POST-TAVR MANAGEMENT**

Post-TAVR Timeframe: From completion of procedure through 30 days post-discharge.

Instructions: Manage and monitor patients who do develop a conduction disturbance.

	If the patient aligns with any of these scenarios	**THEN →**	**Suggested post-TAVR plan**
PPM/ EP STUDY	Symptomatic bradycardia or persistent, complete heart block	→	PPM.
	New, progressive, or pre-existing conduction disturbance that changes post-procedure	→	Monitor, consider EP study and PPM.
	Narrow QRS before and after TAVR	→	EP study and PPM are not indicated.
DISCHARGE	All of the following: ☐ No primary PPM indication ☐ No new 1st degree or 2nd degree AV block ☐ No new bundle branch block ☐ No progression in baseline 1st, 2nd degree AV block or prolongation of the QRS ≥10%	→	Patient can be considered for early discharge.
	If any of the above are present	→	Telemetry until conduction is stable for ≥48 hours; discharge with an outpatient monitor for ≥14 days.
OUTPATIENT MONITORING	New rhythm disturbance (e.g., atrial fibrillation) OR Progression of baseline conduction disturbance OR For whom the provider feels that monitoring is warranted	→	• Discharge with a monitor for a minimum of 14 days. • Care teams should be resourced to manage outpatient monitoring to identify progressive rhythm issues in a timely manner. • Use monitoring system that is accurate, enables adherence, notifies care team in a timely manner.*

*The monitor should have the capacity to notify care teams quickly in the event of DH-AVB. An AEM or implantable loop recorder would suffice provided it has these attributes.
AEM = ambulatory event monitoring, **AV** = atrioventricular, **DH-AVB** = delayed high-grade atrioventricular block, **ECG** = electrocardiogram, **EP** = electrophysiology,
PPM = permanent pacemaker, **TAVR** = transcatheter aortic valve replacement

FIGURE 115.12 American College of Cardiology recommendations for management of bradyarrhythmias after transcatheter aortic valve replacement *(TAVR).* (From Lilly SM, Deshmukh AJ, Epstein AE, et al. 2020 ACC expert consensus decision pathway on management of conduction disturbances in patients undergoing transcatheter aortic valve replacement: a report of the American College of Cardiology Solution Set Oversight Committee. *J Am Coll Cardiol.* 2020;76[20]:2391-2411.)

Although durability will be a continued area of high interest and scrutiny, there is no doubt that TAVR has transformed the field of aortic valve surgery.

TRANSCATHETER MITRAL VALVE REPAIR AND REPLACEMENT

Introduction

Mitral regurgitation (MR) remains one of the most prevalent forms of valvular heart disease in the developed world, affecting over 2 million people in the United States alone.[30] With the FDA approval of several percutaneous treatment options over the past decade, the management of MR has undergone a significant evolution, particularly for patients deemed at high risk for conventional surgical intervention.

In 2013, the FDA approved use of TEER for patients with severe symptomatic primary MR and prohibitively high surgical risk, largely as a result of data from the Endovascular Valve Edge-to-Edge Repair Study (EVEREST II trial).[31] In brief, although surgery was shown to have superior outcomes to TEER, the outcomes and safety profile of TEER were promising enough to offer treatment to nonsurgical candidates. Moreover, 5-year follow-up data showed more comparable data between the two arms, endorsing the durability of MR reduction after TEER.[32] In 2017, the FDA approved use of mitral ViV procedures for failed bioprosthetic valves, offering patients who have too high of a risk for reoperative surgery a viable treatment option. By 2019, the FDA broadened indications for TEER to include symptomatic functional MR irrespective of the surgical risk, drawing on results of the COAPT trial—a randomized control trial between goal-directed medical therapy (GDMT) with and without TEER that showed improved freedom from heart failure–related hospitalizations and all-cause mortality in the TEER arm.[33] Notably, these differences remained in the recently published 5-year follow-up study.[34]

With experience, it has become clear that patient selection is an essential component in the management algorithm. In part catalyzed by the negative results of MITRA-FR—the European equivalent to COAPT—numerous studies have looked into why certain patient subgroups tend to benefit more than others with TEER.[35,36] Namely, several studies have demonstrated evidence for the deleterious effect of severe left or right ventricular impairment, severe pulmonary hypertension, and severe tricuspid regurgitation (TR) on TEER outcomes.[37,38] Moreover, a nuanced understanding of which anatomies are favorable or, conversely, unfavorable or even contraindicated has risen, with most practitioners avoiding TEER in cases of perforated or calcified leaflets, a short posterior leaflet, or large coaptation gaps, for example.

This has in turn paved the way for transcatheter mitral valve replacement (TMVR) as an additional percutaneous treatment option. Less dependent on leaflet anatomy, TMVR has become an increasingly popular treatment option for patients who would otherwise receive TEER but have anatomy that makes repair challenging. Although early results from clinical trials have been promising, larger randomized control trials remain ongoing.[39]

Other ongoing areas of research include the utility of TEER in end-stage heart failure (e.g., bridge to transplant), results with newer-generation devices (EXPAND and EXPAND-G4 trials), off-label use of TMVR in MAC, and efficacy of broadening inclusion criteria for percutaneous interventions in patient who remain surgical candidates (e.g., REPAIR-MR trial).

Current Guidelines

The most recent 2020 guidelines from the American College of Cardiology (ACC)/AHA have incorporated these advancements into their recommendations.[3] TEER is now a class 2a recommendation for the following:

1. Patients with severe secondary MR who remain symptomatic despite optimal GDMT and have left ventricle ejection fraction (LVEF) of 20% to 50% (Fig. 115.13)
2. Nonsurgical candidates with severe primary MR with symptoms or with signs of left ventricle (LV) systolic dysfunction (Fig. 115.14)

Transcatheter mitral ViV is a class 2a recommendation for the following:

1. Symptomatic severe stenosis in nonsurgical candidates
2. Valve regurgitation in the setting of intractable hemolysis or heart failure in nonsurgical candidates (Fig. 115.15)

These recommendations reflect the growing body of evidence supporting the efficacy of percutaneous approaches in improving outcomes in the high-risk surgical population. The guidelines also echo studies that have emphasized the role of patient selection because not all patients with MR will benefit equally from percutaneous interventions. Although the utility of percutaneous procedures in the nonsurgical candidate is well accepted, it will be important to see how results from ongoing studies continue to shape the management of mitral valvular pathology.

Preoperative Evaluation and Imaging

Evaluation for mitral valve intervention generally includes a transesophageal echocardiogram (TEE) and an ECG-gated cardiac CT. A good view of leaflet anatomy and an understanding of the primary pathology are important because transcatheter therapy for primary or functional MR will have different considerations than that for secondary or functional MR. Anatomic predictors of successful TEER include adequate leaflet length (>1 cm) and mobility for substantial coaptation and MR originating from the midportion of the valve. In primary MR, degeneration of the A2 and/or P2 leaflet segments is generally the most successful of TEER cases. When evaluating secondary MR, understanding the primary LV pathology and the amount of any potential scar can give insight into the durability and utility of TEER.[40]

Anatomic limitations to TEER include the following:

- Significant MS
- Mitral valve area <4 cm^2
- Perforated leaflets
- Valve clefts
- Short posterior leaflets (<7 mm)
- Heavily calcified leaflets
- Large coaptation gaps (>1 cm)
- Severe apical displacement of the level of coaptation (>11 mm)
- Severely tethered leaflets

Similar to TAVR, TMVR success depends greatly on preprocedural planning and analysis of echocardiogram and CTA, and all measurements are taken in systole. Exclusions for TMVR include a limiting neo–left ventricular outflow tract (LVOT) size, septal thickness, intraatrial thrombus, prior atrial septal defect (ASD) repair or transeptal approach to mitral surgery, severe patient-prosthesis mismatch, valve dehiscence, and significant PVL. Indications for TMVR are symptomatic, severe bioprosthetic degeneration with either stenosis, regurgitation, or both and are prohibitive risks for repeat surgery. When evaluating mitral stenosis, the mean gradient

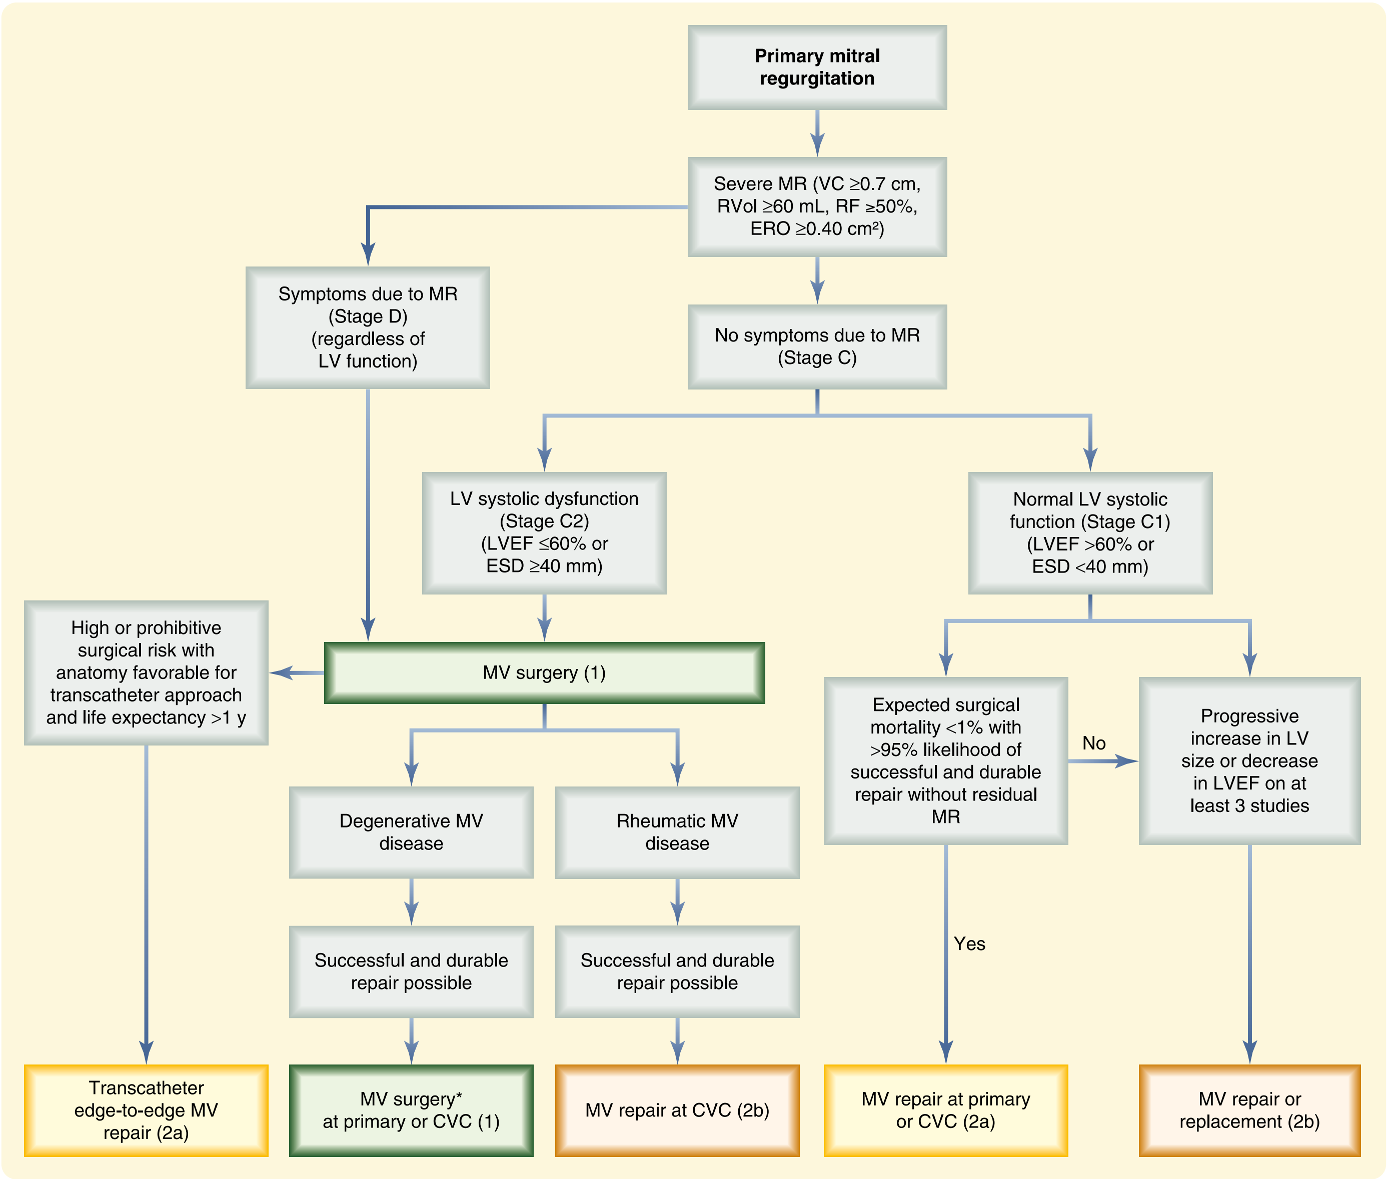
alone cannot be an indication for surgery because it is dependent on volume status, heart rate, diastolic dysfunction, and even left atrial compliance. Symptoms combined with echo findings are critical to determining whether intervention will actually help a patient.

Critical measurements in planning TMVR include the following[41,42]:

- Neo-LVOT area
- Anterior mitral leaflet length
- Inner diameter of existing prosthesis
- Area of existing prosthesis
- LV-mitral annulus angle (Emory angle)
- Aortomitral angle
- Septal bulge
- LV size

Neo-LVOT refers to the narrower, longer LVOT that will result from the anterior mitral leaflet covering the TMVR in that area. It is the smallest area between the septum and most ventricular part of the proposed valve placement. The neo-LVOT area must be adequate to not create obstruction, which is generally >200 mm^2. Additionally, anterior leaflet length is heavily considered in LVOT obstruction risk because a length >20 mm carries a much higher risk (Fig. 115.16). Neo-LVOT obstruction after TMVR, causing a gradient increase much greater than 10 mm Hg, carries a substantial increase in postoperative mortality and, with careful planning, occurs in 2% of ViV and 5% of valve-in-ring TMVR.[42]

Adjunctive techniques to reduce the size of the anterior leaflet or septal bulge in the LVOT can be added to TMVR to increase the size of the neo-LVOT with TMVR. Careful analysis of anterior leaflet length and neo-LVOT at the SAPIEN 3 skirt guides which approach is best. The LAMPOON (laceration of the anterior mitral valve leaflet to prevent LVOT obstruction) procedure uses an electrified wire to puncture through the base of A2 in the anterior leaflet, and the wire is then snared in the LV. As the snared wire is withdrawn, it lacerates the leaflet, creating an opening over the open cells of the SAPIEN 3 in the area of the LVOT. LAMPOON can also be performed in a retrograde manner without puncture



Primary mitral regurgitation
Severe MR (VC ≥0.7 cm, RVol ≥60 mL, RF ≥50%, ERO ≥0.40 cm²)
Symptoms due to MR (Stage D) (regardless of LV function)
No symptoms due to MR (Stage C)
LV systolic dysfunction (Stage C2) (LVEF ≤60% or ESD ≥40 mm)
Normal LV systolic function (Stage C1) (LVEF >60% or ESD <40 mm)
High or prohibitive surgical risk with anatomy favorable for transcatheter approach and life expectancy >1 y
MV surgery (1)
Expected surgical mortality <1% with >95% likelihood of successful and durable repair without residual MR
No
Progressive increase in LV size or decrease in LVEF on at least 3 studies
Degenerative MV disease
Rheumatic MV disease
Successful and durable repair possible
Successful and durable repair possible
Yes

through the leaflet; this requires the presence of a prior ring or valve to serve as a backstop to the cutting wire. Alternatively, if a prominent septal bulge is the limitation, a staged, alcohol septal ablation may reduce the size enough to allow TMVR. This procedure carries a high risk of pacemaker implantation.

Sizing for TMVR varies with anatomy. A mitral ViV app (developed by Dr. Vinay Badwar) can be helpful in sizing and understanding fluoroscopic markers of different valve combinations. TMVR with a SAPIEN 3 valve requires 270 degrees of anchoring material or calcium. Generally, the most atrial part of a surgical valve or ring is measured for sizing. For TMVR in MAC (off-label), the hinge point where the leaflets meet the annulus is measured. A substantial amount of dense calcification is required for valve-in-MAC, with borderline amounts or soft MAC having high risks of valve embolization. Oversizing of the new valve varies with the rigidity of the annulus. A bioprosthetic valve or rigid, complete ring is generally sized 1 to 2 mm over the widest diameter of the annulus. Flexible, noncomplete rings or incomplete MACs are generally more oversized, >20%.[43] Additionally, a significant (>15 degrees) LV-mitral annulus angle (Emory angle) carries an increased risk of PVL, especially with valve-in-ring. A small (<120 degrees) aortomitral angle may increase the risk of LVOT obstruction. Randomized clinical trials comparing ViV TMVR with redo surgical mitral valve repair (MVR) are underway in the REPAIR-MR and CTSNetwork trials.

Mitral Valve Access: Considerations and Steps

Transapical

Initial devices for TMVR were designed for a transapical approach. More recently, newer generations and the majority of

devices for TMVR are now used transeptally because a totally endovascular approach has been shown to have better outcomes. Regardless, transapical access can be a useful tool in rare cases. Transapical access for transcatheter valve replacement is generally done through an anterior left thoracotomy in the fifth intercostal space. CT evaluation of the location of the apex is critical, and the position can often be more lateral and caudal in the setting of cardiomegaly or heart failure. In a non-reoperative setting, the pericardium should be carefully opened and retracted at the apex. In a redo setting, the pericardium may be adhered to the apex, and extensive dissection to free it should be avoided. The exact position of the apex should be palpated and marked. Two perpendicular, full-thickness, pledgeted mattress sutures (3.0 MH) are placed and snared (Fig. 115.17). The apex can then be accessed with a needle and wire, the access is serially dilated, and the sheath is placed under fluoroscopic guidance. When TAVR is complete, the sheath can be removed and the sutures tied in a Trendelenburg position.

Transeptal

TEER and TMVR procedures are generally done under general anesthesia, and they require extensive TEE guidance; the length of procedure can be unpredictable. Critical views on TEE are the bicaval view to demonstrate septal tenting, the aortic short-axis view to locate and avoid the aortic root, and the four-chamber view to assess the puncture height away from the mitral valve.

Similar to arterial access, the femoral vein access for TEER or TMVR can be preclosed with Perclose ProGlide sutures (Abbott, Chicago, IL) for large-bore access. The patient should be heparinized immediately before transeptal puncture, with a goal ACT >250 seconds. The traditional equipment for transeptal access includes an 8-Fr SL1 Mullins sheath (Cook, Bloomington, IN)

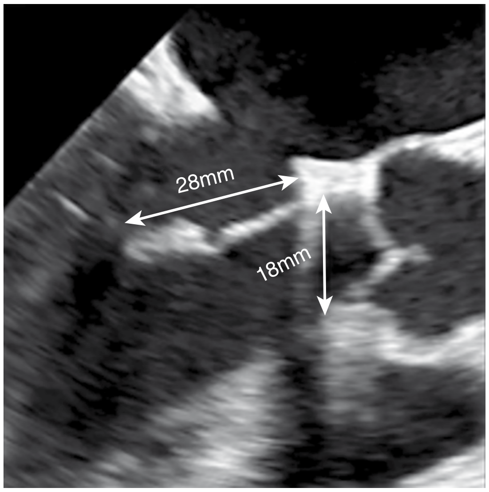

FIGURE 115.16 Anatomy at high risk for left ventricular outflow tract obstruction with transcatheter aortic valve replacement.

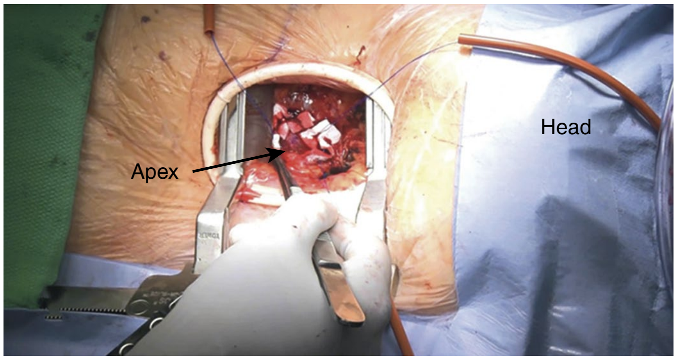

FIGURE 115.17 Transapical access for transcatheter aortic valve replacement. (From Kindzelski B, Mick SL, Krishnaswamy A, et al. Evolution of alternative-access transcatheter aortic valve replacement. *Ann Thorac Surg.* 2021;112[6]:1877-1885.)

and a Brockenbrough BRK needle (Abbott). The BRK needle can be mechanically advanced across the septum or electrified with surgical electrocautery. It is a sharp, open needle with the potential for septal coring and embolism of a small piece of atrial tissue. The radiofrequency transeptal needle, NRG (Baylis Medical, Austin, TX), uses radiofrequency energy to assist in septal crossing. With more specific, instantaneous tissue heating, the NRG needle may offer a safer alternative to the BRK needle.

A critical concept in transeptal access is that the more superior you cross in the fossa ovalis, the more posterior and medial you will approach the mitral valve (Fig. 115.18). The working length of the transcatheter delivery system (5 cm for MitraClip G4) and any distance between the annulus and level of coaptation also play a role in determining the exact optimal transeptal puncture location. A more superior puncture on the septum, and thus posterior approach to the valve, is usually helpful in TMVR, whereas a posterior, midfossa puncture height is generally used for TEER. For these reasons, it is not recommended that an existing patent foramen ovale (PFO) or ASD is used because it will offer an unfavorable approach to the valve.

Advancing the transeptal puncture system over a wire from the femoral vein, the best approach is to start with the steerable sheath in the superior vena cava (SVC). Remove the wire and advance the needle. The needle should remain withdrawn into the sheath until the ideal location for puncture is confirmed. As you pull back, watching the bicaval view, you will see tenting of the septum by the sheath. A pause here to analyze the aortic short-axis and four-chamber views and adjust puncture location is critical. Once the angled sheath is opposed to the fossa ovalis, a clockwise catheter rotation will increase the puncture site height away from the mitral valve, whereas a counterclockwise rotation will decrease the height. Puncture height is measured on the four-chamber view as the distance from the puncture level to the level of coaptation. A minimum of 4-cm puncture height is needed for the majority of TEER and TMVR devices. On fluoroscopy, a left anterior oblique (LAO) view will help visualize crossing right to left, whereas the right anterior oblique (RAO) projection will help to evaluate the puncture site height away from the valve (Fig. 115.19).

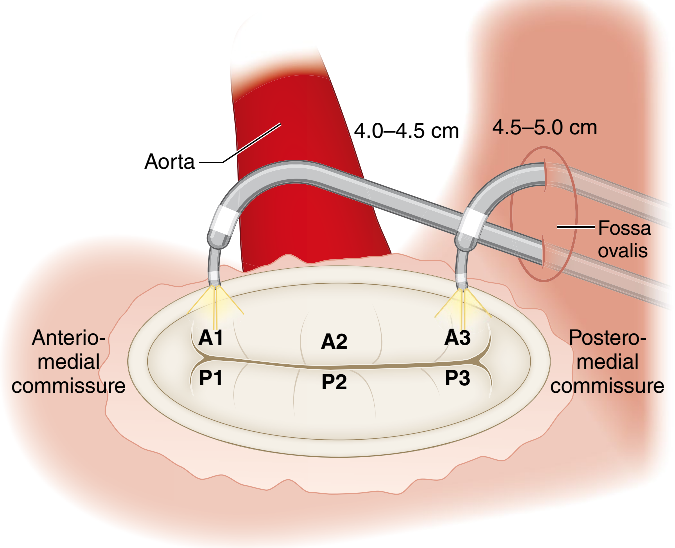

FIGURE 115.18 Transeptal approach to the mitral valve. (Courtesy Abbott.)

Next, the needle is advanced across the septum (mechanically for the BRK needle and with radiofrequency for the NRG needle), as seen on TEE and fluoroscopy. The sheath and dilator are advanced over the wire and into the left atrium (LA), and the needle is removed. If the Mullins sheath will not advance across the septum, a balloon septostomy can be performed with a 5-mm angioplasty balloon. Good LA positioning is then confirmed on TEE and by pressure monitoring. Any catheter and a stiff wire (Amplatz super stiff works well) are then positioned in the left superior pulmonary vein. When working in the LA, it is important that the wires, catheter, and devices are always visualized on TEE to avoid complications.[44,45]

Repair Techniques and Devices

Clips

FDA-approved mitral valve TEER devices include Precision Transcatheter Valve Repair System (PASCAL; Edwards Lifesciences) and the MitraClip G4 (Abbott) (Fig. 115.20).

With the fourth generation of the MitraClip device, there are four size options: NT, NTW, XT, XTW. The NT and NTW have 9-mm-long graspers for a total length of 17 mm. The XT and XTW have 12-mm-long graspers for a total length of 22 mm. The

FIGURE 115.20 MitraClip G4 (Abbott, Chicago, IL) device.

W designation indicates a 6-mm-wide clip rather than the standard 4-mm width. Additional improvements include the ability to grasp each leaflet individually rather than simultaneously. Main considerations when picking a clip size are overall valve size, coaptation gap, and leaflet length.

Although newer, the PASCAL Transcatheter Valve System (Edwards Lifesciences) has been found to be noninferior to the MitraClip. The device similarly consists of paddles (arms) and clasps (grippers) but offers a spacer that helps fill the regurgitant area. The PASCAL system also allows individual leaflet grasping and a wider or narrower size. It retracts to close rather than inverting, which may offer less opportunity to entrap chords. Additionally, it offers a third plane of articulation, allowing for precise positioning. A clinical trial comparing MitraClip to PASCAL for both degenerative and functional MR is currently enrolling.

The anatomic goal of TEER is not to simply attach the two leaflets to each other but to restore a substantial length of coaptation. TEER procedures resulting in short lengths of coaptation have increased residual MR and shorter durability.[46] The ease and success of a TEER procedure are highly dependent on the intraoperative TEE imaging. TEER is not recommended for those with suboptimal TEE windows. After transseptal crossing, the next steps of MitraClip placement are serial dilation of the venous access and advancement of the 24-Fr steerable delivery system 2 cm into the LA. The sheath and all catheters in the LA must be appropriately flushed and de-aired. Additionally, the MitraClip system comes with flush lines, and the system is continually flushed throughout the procedure with heparinized saline. The flush rate is increased when the clip is introduced and again when it is released.

Next, the MitraClip is introduced to the sheath with alignment markers lined up and directed toward the mitral valve, ideally 1 cm above the valve in the area of the MR jet. The clip arms are opened and rotated perpendicular to the intercommissural line, as seen in long-axis TEE view. The clip arms should not be seen in commissural view. Arm position is manipulated in the LA to prevent chordal interference or tethering. Then slight adjustments are made to center above the specific MR pathology using the medial/lateral (M/L) and anterior/posterior (A/P) knobs. The delivery system is secured here, and the clip is advanced across the valve. Positioning is reconfirmed. The LVOT view on TEE will allow visualization of the A/P clip positioning, and the intercommissural view will help with medial-lateral positioning.

Next, the clip arms are partially closed into a grasping angle of 120 to 160 degrees. The clip is withdrawn toward the atrium until the arms catch the leaflet edges. Leaflets can be grasped individually or at the same time. Then the grippers are dropped onto the clip arms to securely attach to the leaflets. The device is closed to the 60-degree position, and anatomy is assessed for MR reduction, clip position and stability, any folds in the leaflets, and mean gradient across the valve (<5 mm Hg). Checking for a reduction in LA pressure can also be a helpful data point at this time. Until this point, the clip is entirely repositionable; the grippers can be lifted and the clip opened.

To release the clip, caps and O-rings on the grippers and clip lock are removed. The gripper line is tested but withdrawing it a few centimeters. Next, the lock line is slowly removed, the release pin is removed, and the actuator knob is turned 8 times in a counterclockwise direction. The delivery system is slowly withdrawn until clip release is seen on fluoroscopy. Lastly, the gripper line is withdrawn, the system is retracted into the sheath, and the final result is assessed. Residual mitral gradient should be less than 5 mm Hg. The result should be 1+ or less MR. Although 1+ MR will occur in 10% to 30%, it is associated with a higher mortality.[47] High residual LA pressure (>15 mm Hg) is a marker for early TEER failure or lower survival after TEER. Residual MR and/or high LA pressure can be treated with a second clip. When placing a second clip, a lateral approach to crossing the valve, with the clip closed, is best to avoid disruption to the first clip. Generally, the transeptal access site does not need to be closed, but closure may be considered in the setting of severe RV dysfunction.

Chordal and Annular Devices

In the United States, transcatheter chordal and annular mitral repair devices remain investigational. Candidates under investigation include the Carillon Mitral valve contour system (Cardiac Dimensions, Kirkland, WA) (EMPOWER trial), which is an annulus cinching device for secondary MR. The Millipede (Boston Scientific) uses intracardiac ultrasound within the device to deploy anchors in the annulus that are then cinched together. Feasibility studies for this device have completed enrollment. Another promising annuloplasty device is the Cardioband Mitral System (Edwards Lifesciences), which is an adjustable posterior annular band placed transseptal. The Mitralign (Mitralign Inc, Tewksbury, MA) contains a pair of transeptally placed pledgeted sutures used to plicate the posterior annulus of the mitral valve. Both the Neochord Artificial Chordae Delivery system DS100 (Neochord Inc, St. Louis Park, MN) and the HARPOON beating-heart MVR system (Edwards Lifesciences) (RESTORE trial) are transapically placed chordal replacement systems for degenerative MR undergoing clinical trial in the United States (Fig. 115.21).[48]

Replacement Techniques

Valve-in-Valve

Patients with anatomies not suitable for TEER or with prior surgical mitral valve replacement often have TMVR options. Currently, the only FDA-approved TMVR device is SAPIEN 3 for valve-in-ring or ViV TMVR. As mentioned, the greatest procedural risk with ViV TMVR is LVOT obstruction, which can be mitigated by careful planning and adjunctive procedures.

Additional access needed to facilitate TMVR includes contralateral venous access for transvenous pacemaker placement and femoral arterial access for aortic pressure monitoring. The Edwards eSheath is typically introduced before transseptal puncture and after heparinization. Depending on anatomy, a mid- to inferior and posterior puncture in the fossa ovalis is best, with a goal puncture height of 3 to 4 cm. Then, exchange the Mullin sheath for an Agilis Nxt steerable sheath (Abbott) to help direct the wire to the valve. The valve is crossed and replaced with a pigtail catheter, and a transvalvular gradient is checked. LA pressure and an LVOT gradient are checked as well. Next, a stiff wire is placed in the left ventricular apex. TMVR typically requires septostomy

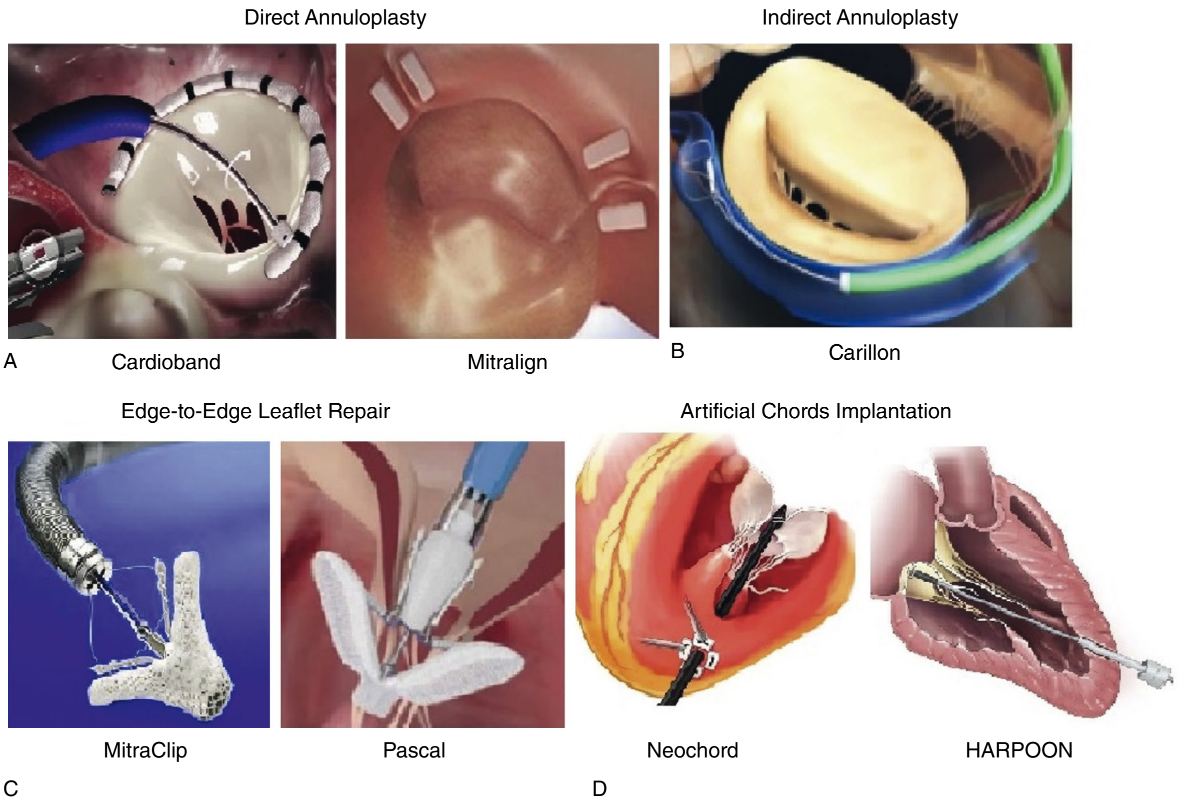

FIGURE 115.21 (A–D) Available and emerging devices for transcatheter mitral valve repair. (From Kosmas I, Aravanis N, Iakovou I, et al. Transcatheter management of valvular regurgitation beyond the aortic valve (mitral-tricuspid valve): literature overview and future perspectives. *Hellenic J Cardiol.* 2020;61[5]:299-305.)

with a 12- to 14-mm balloon to get the SAPIEN valve through the septum, which is best done after crossing the valve. Biplane fluoroscopy can be helpful, with RAO showing the anterior-to-posterior view of the mitral valve. Any ancillary procedures should be done at this point.

It is critical to mount the SAPIEN 3 so that the skirt is in the atrium (opposite to TAVR) as well as to introduce the delivery system with the Edwards "E" logo facing down (opposite of TAVR) to allow flexion of the delivery toward the mitral valve. Achieving coaxial alignment within the failed surgical valve can be a challenge and is critical for precise deployment. Malalignment can sometimes be adjusted with a subtle rotation of the flex knob or a push in on the delivery system. Once the SAPIEN is across the mitral valve and the pusher is withdrawn, the valve is deployed under rapid ventricular pacing. The ideal depth of implantation placement is 80% atrial, 20% ventricular, 90/10 if the LVOT is marginal. The valve will foreshorten from the atrial side. Implantation depth should be adjusted to ensure the entire annulus is touching the external skirt of the SAPIEN 3 valve.[41] When possible, with the newer-generation SAPIEN valves, any commissures of the SAPIEN should be directed away from the LVOT. Deployment is slower than with TAVR to allow microadjustments to be made to position and alignment of the TMVR.

After deployment, the valve should be assessed while wire access is maintained. Any PVL, underexpansion of the valve, or high residual gradient can be treated with a postdeployment balloon valvuloplasty, either with the Edwards deployment or a more noncompliant balloon. An effective orifice area <1.2 cm^2/m^2 necessitates another balloon valvuloplasty. Sometimes PVL can be resolved with a flaring of the TMVR on the ventricular side. Lastly, the direction and size of the interatrial shunt should be examined and closure considered in the setting of RV dysfunction.[49]

Valve-in-Ring and Valve-in–Mitral Annular Calcification

Valve-in-ring and valve-in-MAC procedures add additional considerations and complexity and have much poorer outcomes compared with ViV TMVR. Considerations particular to valve-in-ring placement include not only the size and radiopaque markers of ring used but also the flexibility (rigid, semirigid, flexible), completeness, and shape. Rigidity affects the ability of the annulus to become circular with TMVR. The valve-in-ring or valve-in-MAC approach requires 270 degrees of rigid contact between valve and annulus to anchor the device. Therefore, complete rings work best to anchor the TMVR, and heavily calcified, continuous MAC is required rather than soft or caseous MAC. However, rigid rings with significant eccentricity will have significant risk of distorting the SAPIEN 3 valve and early failure. Complete, semirigid rings generally have the best result because they can anchor the TMVR but become more circular. TMVR in rigid rings should be sized 1 mm over the widest diameter of the prosthesis because oversizing can lead to valve distortion. For softer landing zones, such as a flexible ring or MAC, oversizing of 20% or more is recommended. Again, the mitral ViV app can be helpful in sizing.[43,50]

Similar to ViV, the neo-LVOT or skirt neo-LVOT, anterior leaflet length, and trajectory of the valve and stiff wire need to assess the risk of LVOT obstruction. The annulus and leaflet lengths should be measured at the exact insertion point of the leaflets on the annulus. Emory angle matters much more valve-in-ring compared with ViV. With an Emory angle >15 degrees, the TMVR valve will not be coaxial to the ring and will lead to malalignment and PVL. This can sometimes be overcome with a push inward during deployment to direct the valve inflow more septal or with a clockwise rotation to move the atrial portion more posterior. In adjusting alignment, small changes in the atrial side of the valve can be made with the flex in the delivery system, whereas small adjustments to the ventricular side of the valve are made with more or less tension on the stiff wire. However, if trajectory is predicted or ends up being suboptimal, advanced techniques such as a transapical rail or POULEZ (preparation of U-stitch to correct lateral deflection for endovascular mitral valve replacement in a short landing zone) can be added to the procedure to improve alignment.

When using the SAPIEN 3, as opposed to the SAPIEN 3 Ultra, which has a shorter sealing skirt, some operators choose to sew additional polytetrafluoroethylene patch (Gore, Phoenix, AZ) onto the valve to elongate the skit and increase sealing area. This can also allow the valve to be implanted a few millimeters more atrial if LVOT obstruction is a concern. When this modification is used, the valve needs to be crimped onto the balloon rather loaded in vivo. This allows the opportunity to orient the commissures. By directing a commissure to 12 o'clock on the delivery system, it will be directed away from the LVOT.

When the TMVR is aligned orthogonal to the landing zone, the remainder of the procedure is similar to ViV TMVR. Goal implantation depth is also 80%/20% (ventricular/atrial), unless an additional sealing patch has been added, in which case the TMVR can be more atrial. Unlike ViV TMVR, postdeployment ballooning is more likely to change the position of the new TMVR when used valve-in-ring or valve-in-MAC.[41,43]

Emerging Devices

There are currently no approved mitral valve–specific devices for TMVR, although many are proving very promising in clinical trials. The Intrepid valve (Medtronic) is a 27-mm bovine valve surrounded by a nitinol, self-expanding frame with fixation anchors that has been evaluated in the APOLLO trial. Initially a transapical device, a transseptal version is now being studied. The Tendyne valve (Abbott) is a transapically placed, completely retrievable, bovine pericardial valve with high conformability to the mitral annulus as well as a transapical tether. The Tendyne valve is under investigation in the SUMMIT (clinical trial to evaluate the safety and effectiveness of using the Tendyne Mitral Valve System for the treatment of symptomatic MR) trial. Edwards Lifesciences has developed a SAPIEN M3 system consisting of a docking component that encircles the leaflets above and below the annulus to create a landing zone. The valve implanted uses similar design and tissue as the SAPIEN 3 for TAVR; however, the entire frame is covered with a sealing skirt. Study is underway in the ENCIRCLE trial. Additionally, more exhaustive study using the SAPIEN 3 valve in the mitral position is underway in the MITRAL II (Mitral implantation of transcatheter valves) trial.

Medical Management

The typical length of stay is 1 to 2 days. A predischarge transthoracic echocardiogram (TTE) is prudent to check for complications, then annual monitoring thereafter. There are no guidelines directly addressing medical management after TMVR. Subclinical leaflet thrombosis using the SAPIEN 3 for TMVR is reported to be higher than in TAVR.[42] Registry studies have reported their results using lifelong aspirin and a minimum of 3 months of anticoagulation, similar to surgical MVR. Dual-antiplatelet therapy rather than anticoagulation has been shown to have higher rates of valve thrombosis. Many use intravenous heparin and subcutaneous Lovenox until a therapeutic international normalized ratio (INR) is reached.

This likely contributes not only to lower rates of valve thrombosis but also prevention of access-related venous thrombus from embolizing and potentially crossing the septostomy site.

PERCUTANEOUS TRICUSPID INTERVENTION

Introduction

With the increasing use of percutaneous approaches to aortic and mitral valve pathology, a renewed interest in the often "forgotten" tricuspid valve has been growing over recent years. Multiple studies have shown that TR is vastly undertreated and that its natural course is unfavorable, with high mortality rates.[51] Moreover, TR is becoming increasingly prevalent in our aging society. Indeed, many of these patients are often elderly and frail, with comorbidities that put them at high or even prohibitive risk for surgical repair. As a result, advancements in percutaneous heart procedures have paved the way for new transcatheter-based approaches to repair and replacement of the tricuspid valve in the high-risk patient.

Given the recency of its advent, percutaneous tricuspid valve interventions are numerous and diverse. Although there are many different devices currently being tested, they can generally be grouped into repair and replacement options. Within repair options, there are generally TEER and annuloplasty techniques. Replacement options almost always refer to orthotopic replacement, but there have been cases of heterotopic unicaval or bicaval deployment as well.[52]

Current Guidelines

The most recent guidelines from the ACC/AHA in 2020 recommend tricuspid valve surgery for severe TR at time of left-sided surgery (class I), with primary TR (class 2a), and with secondary TR that is poorly responsive to GDMT and without increased pulmonary pressures or left-sided disease (class 2a).[5] They also recommend surgery for progressive TR at time of left-sided surgery if annular dilation is greater than 4 cm or there is prior right-heart failure (class 2a). Class 2b recommendations for surgical intervention include severe TR with symptoms, prior left-sided valve surgery, and absence of severe pulmonary hypertension or RV systolic dysfunction as well as asymptomatic severe primary TR with progressive RV dilation or systolic dysfunction.

Notably, given the recency of transcatheter-based approaches, these guidelines have no significant mention of such approaches and how they should be weighed alongside surgical intervention. Moreover, with recent studies showing that TR can be further classified into massive and torrential regurgitation and that secondary TR is actually quite variable,[53] these guidelines insufficiently capture important nuances in the variability of TR pathology. The only mention of transcatheter-based approaches to tricuspid pathology in published guidelines to date is in the European Society of Cardiology (ESC)/European Association for Cardio-Thoracic Surgery (EACTS) guidelines on valvular disease from 2021, which designates transcatheter treatment of symptomatic secondary severe TR in inoperable patients at a center of expertise as a class 2b recommendation.[6] Indeed, given the recency of percutaneous tricuspid interventions, current guidelines have yet to incorporate the growing literature in this area, with numerous clinical trials actively ongoing.

Clinical Trials

With the lack of guidelines, most institutions rely on trial-specific inclusion criteria in determination of clinical indication for percutaneous intervention. The recently published TRILUMINATE Pivotal trial used the following inclusion criteria in its randomized study[54]:

1. Subject has been adequately treated and stable for at least 30 days, as follows:
   - Optimized medical therapy for treatment of TR (e.g., diuretics)
   - Medical and/or device therapy for MR, AF, coronary artery disease, and heart failure
2. Subject is symptomatic with severe TR despite being optimally treated as described. TR severity is determined by the assessment of a qualifying transthoracic echocardiogram and confirmed by transesophageal echocardiogram.
3. The cardiac surgeon of the site's local heart team concurs that the patient is at intermediate or greater estimated risk for mortality or morbidity with tricuspid valve surgery.
4. New York Heart Association (NYHA) functional class II or III or ambulatory class IV.
5. Femoral vein access is determined to be feasible and can accommodate a 25-Fr catheter.
6. Age ≥18 years at time of consent.

In other words, most patients undergoing percutaneous procedures at present have at least severe TR, have failed medical therapy, are at high or prohibitive risk for surgical intervention, and are not undergoing another cardiac surgery.

Building off promising, early single-arm data,[55] the TRILUMINATE Pivotal trial was one of the first major prospective randomized control trials for TEER, comparing Abbott's TriClip device to medical therapy. With 350 patients enrolled at a mean age of 78 years, the clinical trial showed a significantly higher Kansas City Cardiomyopathy Questionnaire (KCCQ) quality-of-life score and higher percentage of TR severity reduction at 30 days, with persistent trends at 1 year. Notably, 98.3% of patients who underwent percutaneous repair were free from major adverse events at 30 days. However, the incidence of death and rate of hospitalization for heart failure did not appear to differ between the two groups. Data from the single-arm CLASP trial showed similar outcomes at 1 year, albeit with the Edwards PASCAL device.[56,57] Out of the 46 patients who completed 1-year follow-up, 5 (7.7%) died from cardiovascular causes, and 11 (16.9%) had an event of severe bleeding. There were significant improvements in both functionality and quality-of-life scores.

In terms of replacement options, the TRISCEND trial was a pivotal study in the context of percutaneous tricuspid interventions. A single-arm assessment of the Edwards EVOQUE valve (Fig. 115.22), the trial demonstrated promising preliminary results, with device success at 94%; significant reduction in heart failure–related hospitalization, with freedom of 88% at 1 year; and significantly improved functional and quality-of-life scores.[58] Importantly, rate of severe bleeding was relatively high at 25.5%, which was attributed to postoperative anticoagulation regimen. The prospective, multicenter TRISCEND II pivotal randomized trial is ongoing and will provide further insight on how to contextualize these initial results.[59]

Preoperative Evaluation and Imaging

It is important to recognize that there are key anatomic differences between the mitral and tricuspid positions that make both transcatheter tricuspid valve replacement (TTVR) and tricuspid repair techniques uniquely challenging. Regarding TTVR, unlike the aortic and mitral positions, there is no calcium to assist with sealing, so there is arguably a narrower therapeutic window regarding undersizing (i.e., embolization) and oversizing (i.e., heart block).

FIGURE 115.23 There is significant variability in leaflet structure, size, and number in the tricuspid valve. (From Hahn RT, Weckbach LT, Noack T, et al. Proposal for a standard echocardiographic tricuspid valve nomenclature. *JACC Cardiovasc Imaging*. 2021;14:1299-1305.)

Because of increased trabeculation of the RV compared with the LV, there is less depth and therefore less maneuverability of devices. Regarding tricuspid repair techniques such as TEER, given the lower-pressure environment, leaflets are thinner and more fragile. There is greater variability in the leaflet structure, size, and even number on the tricuspid side,[60] making techniques that rely on leaflet coaptation, such as TEER, particularly challenging (Fig. 115.23).

For both techniques, the lack of septal support and the variability of the angle between the IVC and tricuspid annulus can further complicate repairs done via transfemoral approach, which is currently the most common because of the relatively large-caliber size of most devices. Indeed, given that these devices are essentially free-floating in the right atrium, successful coaxial deployment of valve replacement options and maneuverability of repair devices are highly dependent on the relative angle of the tricuspid annulus.

Another aspect that may complicate intervention is the presence of intracardiac leads. In addition to restricting access to the tricuspid valve or RV, leads may cause shadowing on echocardiography and limit visualization during the procedure. In patients who are not pacer dependent, these factors may prompt lead extraction before intervention.

Because of the anatomic challenges unique to percutaneous tricuspid valve interventions, preoperative evaluation and imaging are essential for procedural planning. All patients being considered for percutaneous tricuspid intervention should have a preoperative clinic visit in which detailed history and physical exam are obtained. Particular attention should be paid to symptoms (e.g., fatigue, shortness of breath, peripheral edema), functionality (including fall risk), and medical management (i.e., diuretics). Routine preoperative laboratory testing, including complete blood count, basic metabolic panel, and coagulation studies, should be obtained.

A preoperative electrocardiogram and transthoracic echocardiogram should be obtained. In addition to detailed assessment of the pathologic tricuspid valve, all other heart valves should be closely interrogated. A gated CTA of the chest should also be obtained preoperatively. With advanced 3D processing capabilities, cardiac imaging specialists can comment on annular size and shape, papillary muscle location, right atrial and ventricular depth, venous patency, and atriocaval angles—all important factors to consider when planning out the procedure. In certain cases, a preoperative TEE may also be necessary to assess feasibility of intervention because intraoperative TEE is often used for device deployment. There have been attempts to develop a scoring system based on preoperative imaging to improve patient selection for procedural success, but none has yet been validated on a large scale.[61]

Techniques

Access

The majority of repair and replacement options are approached via femoral venous access because of the large size of most delivery systems. However, internal jugular venous access is an option for smaller-profile systems. Because the majority of these patients have at least severe TR, the vein is often quite large. On ultrasound, one may even see pseudo-pulsation of the vessel from the regurgitation, so it is important to distinguish from the common femoral artery via transient compression with the probe.

Because of the large size of many percutaneous systems (>40 Fr), it is important to take steps to avoid significant blood loss. Using Perclose devices in preclose technique is a common technique for arterial access, but because of the thinner nature of veins, this technique can be more difficult for venous access. Other closure devices are usually too small to engage such a large defect. Of course, manual compression is a feasible option for essentially all venous access. At our institution, we prefer placing a large purse-string stitch to cinch closed the access site and apply manual compression thereafter, removing the stitch before discharge from the hospital.

Repair

The first percutaneous approaches to tricuspid valve repair adapted preexisting technology for the mitral valve, namely, TEER. Inspired by the surgical Alfieri stitch—which fixes two points from opposing leaflets to create a double-outlet valve with decreased orifice area—this transcatheter-based technique has been translated to the tricuspid valve, most often clipping the anterior and septal leaflets. Although there are numerous TEER devices available, the most commonly being investigated in clinical trials are the Edwards PASCAL system and the Abbott TriClip systems.[54–57,62] Most devices use transfemoral venous access. Once the delivery system is at the level of the right atrium, the clip apparatus is delivered, and the system is flexed to position the clip coaxial to the tricuspid valve annulus. Intraoperative TEE is used to assess the precise position of the clip, most often aligning it to the anterior-septal coaptation line. Once satisfied with the positioning, the device is advanced into the RV. Once leaflet capture is confirmed on TEE, the clip is released, and the severity of TR is reassessed. Often, more than one clip may be necessary. In addition to TEER, there are numerous percutaneous annuloplasty repair options. One example is the K-Clip (Fig. 115.24), which clamps the enlarged annular tissue with a clip to reduce the perimeter of tricuspid annulus, similar to annular plication.[63] Other systems include a direct annuloplasty repair device with anchors that pass through the annulus into the ventricle and a percutaneous annular ring device. Several are enrolling in ongoing studies, but none of these options yet has convincing data on par with the TEER options.

Replacement

Another technique with growing popularity is TTVR. Bypassing some of the nuanced complexities of tricuspid leaflet-based repairs, some believe TTVR to be a less complex, more generalizable technique for the diverse anatomy of the tricuspid valve. However, there has yet to be any significant evidence showing superiority of one technique over the other. There are numerous devices within this category as well, with the EVOQUE valve currently having the most data.[58,59,64] One challenge with this particular valve, however, is its dependence on complete capture of most of the leaflets. Because the valve is secured solely by prongs that attach to the leaflets, it is crucial to ensure each

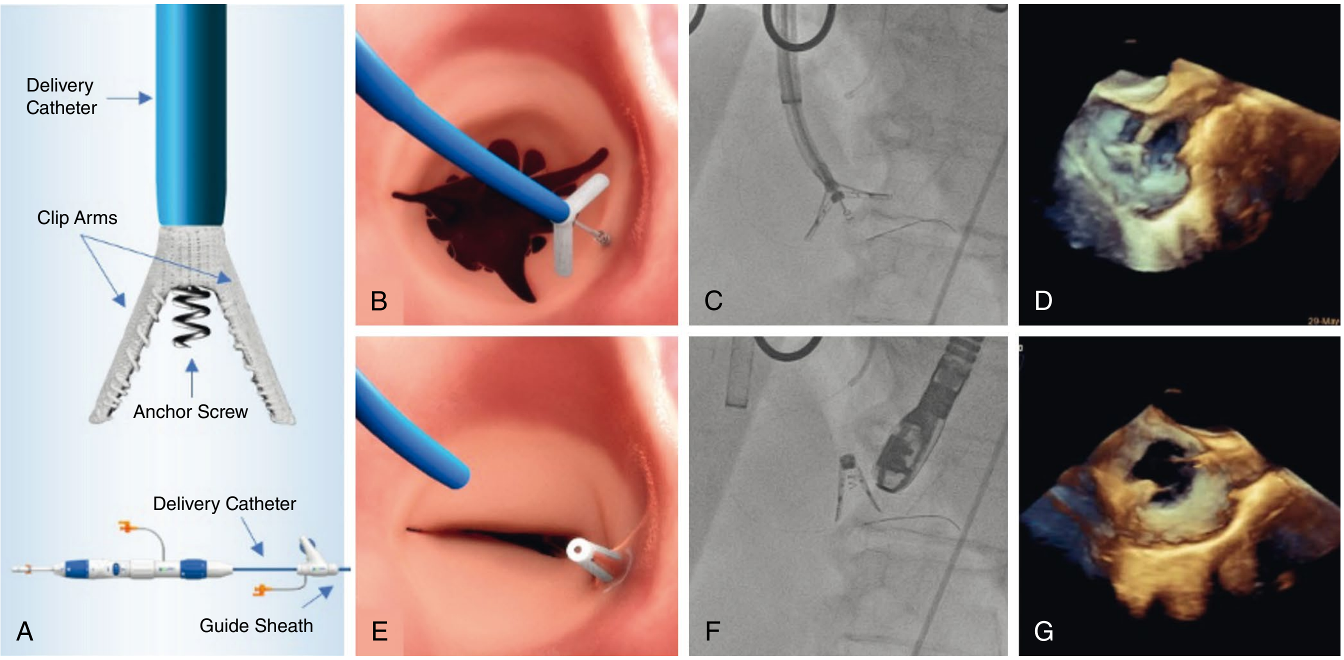

FIGURE 115.24 (A–G) Transcatheter K-Clip tricuspid valve annuloplasty system by Huihe Company, China. (From Zhang X, Jin Q, Pan W, et al. First-in-human study of the K-Clip transcatheter annular repair system for severe functional tricuspid regurgitation. *Int J Cardiol.* 2023;390:131174.)

prong is attached to a leaflet before device release to avoid PVL or even embolization. However, this can be quite difficult, especially if intraoperative imaging is not optimized. This limitation has made alternative options, such as the Medtronic Intrepid valve—a dual-stent system with a bovine pericardial valve that does not require extensive leaflet capture—more attractive.

In several case reports, use of heterotopic valve replacement in the vena cavae has been documented (Fig. 115.25).[65,66] This technique was used in part when the native annulus was larger than available devices could accommodate. However, with early failure of the TRICAVAL randomized control study as a result of high rates of valve dislocations, the technique has declined in popularity over the years and remains limited to rare compassionate-use cases.[67]

Conclusion

Percutaneous tricuspid valve repair and replacement options are becoming increasingly popular options for high-risk patients with significant TR. The anatomy of the tricuspid valve presents unique challenges to both approaches. The results from recent clinical trials and other studies have shown promising short-term outcomes with high success and efficacy rates, but there have also been significant bleeding complications noted from anticoagulation regimens. Results from ongoing clinical trials will be important in shaping this dynamic, exciting landscape.

ATRIAL FIBRILLATION ABLATION

Introduction

Although cardiothoracic surgeon involvement in the treatment of AF is not strictly percutaneous, recent developments in the hybrid ablation of AF, combining minimally invasive surgical epicardial ablation with endocardial catheter ablation, fit well into an electrophysiology (EP)-centered heart team approach, similar in spirit to the widely accepted heart team approach to valvular heart disease. The scope of the problem exceeds that of valve disease, with estimates of global prevalence of 60 million cases and a lifetime risk of developing AF of 33%.[68] Disease burden is high for this prevalent arrhythmia, with numerous studies demonstrating an association between AF and excess mortality, stroke, heart failure, cognitive decline, depression, lower quality of life, and increased hospitalizations.[69] Partnering with electrophysiologists to deliver the most effective treatments for AF is thus paramount.

Current clinical guidelines make a distinction between the treatments recommended for paroxysmal, persistent, and long-standing persistent AF as defined in Table 115.3, and it is important for the cardiothoracic surgeon to appreciate the classification of AF to align the mental construct of the disease between surgeons and cardiologists and electrophysiologists. *Permanent AF,* from the standpoint of the proceduralist, should be reserved for only the worst cases unlikely to respond to intervention because the term represents a mutually agreed acceptance of failure to achieve rhythm control. Although this nomenclature framework is useful to clinically describe AF, the exact mechanisms underlying the pathogenesis of AF are incompletely understood, and clinical terminology does not directly relate to underlying mechanisms in the individual patient, underscoring the value of a multidisciplinary approach to the treatment of this disease.

Guidelines

In the guidelines for the treatment of AF, the role of the cardiothoracic surgeon is fairly limited as of the writing of this textbook. The management of AF largely has traditionally revolved around reducing stroke risk with oral anticoagulation and either a pharmacologic rate-control strategy or a pharmacologic rhythm-control strategy. Catheter ablation to maintain normal sinus rhythm is typically reserved for treatment of symptomatic AF that is refractory to pharmacologic treatment, and even more invasive

TABLE 115.3 **Clinical Classification of Atrial Fibrillation (AF)**

Paroxysmal	AF that terminates spontaneously or with intervention within 7 days of onset
Persistent	Continuous AF that lasts longer than 7 days
Long-standing persistent	Continuous AF that lasts >12 months
Permanent	A term used to describe AF when the patient and clinician make a joint decision to stop further attempts to restore and/or maintain sinus rhythm

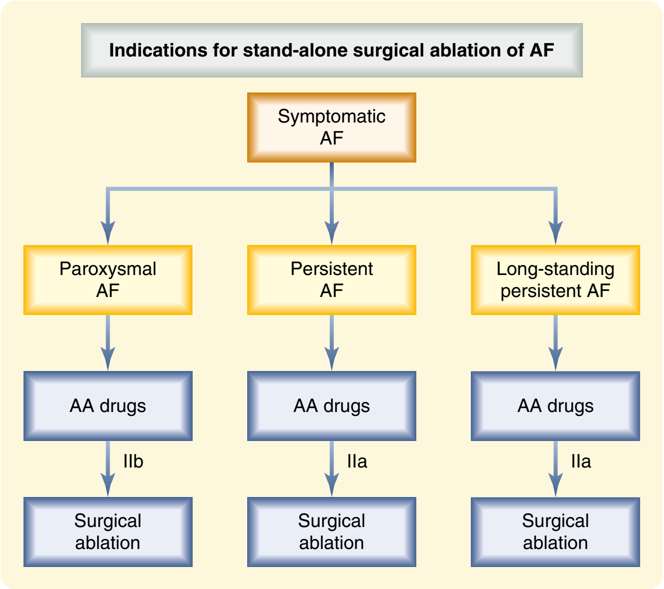

FIGURE 115.26 Heart Rhythm Society consensus statement diagram illustrating the strength of indication for stand-alone surgical ablation, including hybrid ablation techniques of atrial fibrillation *(AF). AA,* Antiarrhythmic. (From Calkins H, Hindricks G, Cappato R, et al. 2017 HRS/EHRA/ECAS/APHRS/SOLAECE expert consensus statement on catheter and surgical ablation of atrial fibrillation: executive summary. *Heart Rhythm.* 2017;14:e445-e494.)

ablation beyond percutaneous, catheter-based techniques by the electrophysiologist has no class I indication in the current guidelines from the AHA/ACC/Heart Rhythm Society or the ESC, which published their most recent guidelines in 2014 and 2020, respectively. The Heart Rhythm Society publishes and periodically revises a consensus statement, most recently in 2017, and concurs regarding class I recommendations for ablation. At best, surgical ablation in the absence of concomitant valvular disease receives either IIa or IIb recommendations, but only after failure of antiarrhythmic drugs (Fig. 115.26).[70] These documents are, however, currently being revised, and the data have accumulated demonstrating benefit of ablation and rhythm control as first-line therapy, as detailed in the following section.

The utility of a rhythm-control-first approach is slowly gaining traction over the rate-control-first strategy that dates almost a quarter century back to the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial. In the EAST-AFNET 4 trial, published in the *New England Journal of Medicine,* patients randomized to a rhythm-control strategy first with either ablation or pharmacotherapy compared with rate control and anticoagulation as usual care were associated with a lower rate of the primary outcome by a hazard ratio of 0.79 (96% confidence interval [CI] 0.66–0.94).[71] The composite outcome included death from cardiovascular causes, stroke, or hospitalization with worsening heart failure or acute coronary syndrome.

Regarding an ablation-first approach, many randomized controlled trials have recently been completed that demonstrate improved efficacy of ablation compared with pharmacologic therapy with improved quality of life and reduced hospitalizations. The EARLY-AF trial, published in the *New England Journal of Medicine,* randomized patients with symptomatic paroxysmal AF to either cryoballoon ablation or medical therapy as first-line treatment and found a lower incidence of progression to persistent AF, a lower rate of recurrent tachyarrhythmias, and a reduced rate of hospitalization during 3 years of follow-up.[72] In the STOP AF First Trial, cryoballoon ablation was found to be more effective at maintaining sinus rhythm when randomized against antiarrhythmic drugs as first-line treatment for symptomatic paroxysmal AF.[73]

Furthermore, in the specific population of patients with heart failure, catheter ablation has been shown to improve mortality in two high-profile randomized controlled trials. In CASTLE-AF, 363 patients with NYHA class II or greater congestive heart failure and EF <35% were randomized to catheter ablation versus medical therapy. After a median follow-up of approximately 3 years, patients randomized to catheter ablation had lower composite end point of death from any cause or hospitalization for heart failure. Impressively, all-cause mortality analyzed on its own as a secondary end point was also significantly lower in the catheter ablation group, with an absolute reduction of 11.6%.[74] Similarly in a prespecified subgroup analysis of the CABANA trial, patients with NYHA class II heart failure had a 43% relative reduction of all-cause mortality after approximately 4 years of follow-up.[75]

Finally, and most relevant to the cardiothoracic surgeon, combining epicardial, minimally invasive surgical ablation with endocardial, catheter-based ablation has been shown in three separate randomized controlled trials to be superior to catheter-based ablation alone. The first of these compared a hybrid subxiphoid surgical approach with subsequent catheter ablation, also known as the *Convergent procedure.* In the Converge trial, patients randomized to hybrid surgical-catheter ablation had a 53.5% freedom from atrial arrhythmias off antiarrhythmic drugs compared with 32% in the catheter ablation arm.[76] The results using a video-assisted thoracoscopic surgical approach are even better. In the CEASE-AF trial, patients randomized to a bilateral video-assisted thoracic surgery (VATS)-based hybrid surgical-catheter ablation had 71.6% primary effectiveness versus 39.3% in the group with catheter ablation alone through 12 months of follow-up.[77] In a smaller randomized trial comparing unilateral VATS-based hybrid ablation with catheter ablation alone, freedom from atrial tachyarrhythmias without the need for antiarrhythmic drugs at 1 year was 89% versus 41% in favor of hybrid ablation.[78] Each of these hybrid ablation trials enrolled persistent and long-standing persistent patients only.

Given the relative weakness of recommendation for surgical ablation; the accumulating data demonstrating benefit of ablation to maintain normal sinus rhythm, including better mortality for patients with heart failure; and the randomized data demonstrating superiority of a hybrid approach to catheter ablation alone, it is imperative that the cardiothoracic surgeon become familiar with and embrace hybrid ablation techniques. Adequate surgeon involvement in a heart team–based approach to the treatment of AF will ensure better outcomes for the individual patient and will likely influence the revision of the relatively out-of-date clinical guidelines for the effective treatment of AF.

Surgical ablation at the time of concomitant surgery has a class IIa recommendation and is beyond the scope of the current chapter.

Procedural Considerations

Hybrid ablation of AF combines either a subxiphoid approach or a video-assisted thoracoscopic approach with catheter-based ablation, either at the same time as the surgical procedure or staged at a later hospitalization. The goal for both methods is to achieve

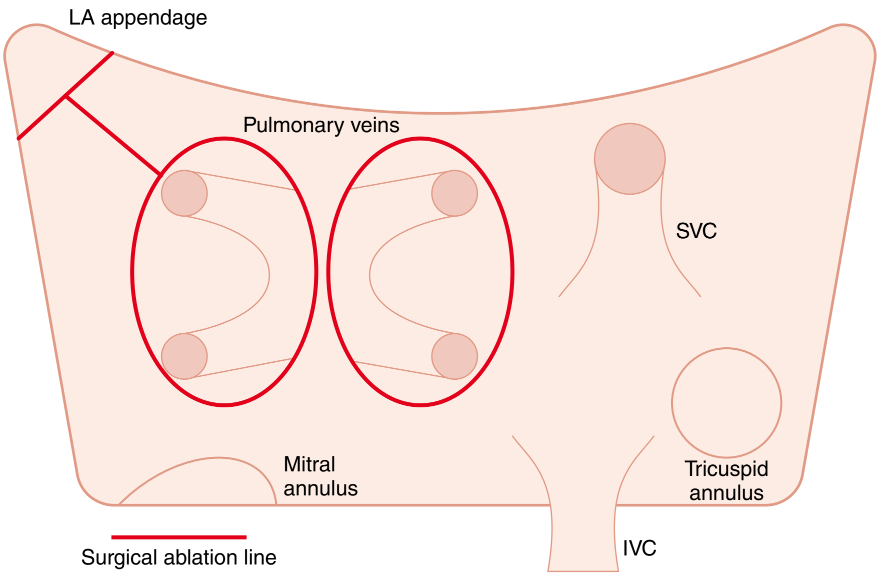

FIGURE 115.27 Schematic of the lesion set performed at our institution via a left video-assisted thoracoscopic surgery approach. Left-sided and right-sided pulmonary vein isolation are achieved separately with a bipolar radiofrequency clamp, and connecting lesions are created epicardially with a radiofrequency ablator between the superior veins and inferior veins separately. The left atrial *(LA)* appendage is clipped, and an epicardial line is created from the left superior pulmonary vein to the base of the appendage to prevent reentry around the clipped appendage. *IVC,* Inferior vena cava; *SVC,* superior vena cava.

isolation of the posterior wall of the LA, as shown in Fig. 115.27. The advantage of a hybrid approach is that by combining an epicardial with an endocardial ablation of the same segment of atrial tissue, a more durable and/or more completely transmural lesion can be created.

An important semantic consideration when describing a hybrid ablation is to avoid calling the lesion set a *Cox-Maze procedure.* The literature is replete with modified Mazes, mini-Mazes, and numerous other variations. Given significant variability in freedom from AF, confusion regarding the anticipated results of a Cox-Maze procedure has arisen, and because many modified lesion sets have particularly poor results, distrust of all things called "Maze" has arisen in the minds of many cardiologists. Cardiothoracic surgeons have thus had to fight an uphill battle to get a foothold in the treatment paradigm for AF. Similarly, hybrid ablations, as described hereafter, are not "hybrid Maze" procedures. They are hybrid ablations.

The subxiphoid approach, commonly called the *Convergent procedure,* combines epicardial ablation via a subxiphoid incision with the aid of a scope and a purpose-designed cannula similar in design to a mediastinoscope. This is combined with a catheter-based pulmonary vein isolation to achieve isolation of the posterior wall. The subxiphoid approach gives the operating surgeon access to the posterior wall between the pericardial reflections encircling the pulmonary veins and the superior aspect of the posterior LA. Posterior wall isolation can then be achieved in the electrophysiology (EP) suite with a catheter-based pulmonary vein isolation and additional ablation connecting the right superior to the left superior pulmonary vein above the pericardial reflection.

VATS-based approaches, on the other hand, involve a more extensive ablation by the cardiothoracic surgeon, typically through a bilateral VATS approach. The increased access to the LA through this approach allows for complete bilateral pulmonary vein isolation with a bipolar radiofrequency clamp and preliminary completion of the posterior wall isolation by epicardial ablation to connect the superior and inferior aspects of the posterior left atrial wall, the roof and floor of the LA from an EP perspective. VATS access also allows for the surgeon to place a clip on the left atrial appendage. Left atrial appendage occlusion has been shown to reduce thromboembolic events after open cardiac surgery.[79]

Preoperative Imaging and Evaluation

As opposed to the typical patient referred for the surgical treatment of cardiac disease, a patient referred primarily for ablation of AF may not have comprehensive imaging. Some patients may not have had a recent echocardiogram to evaluate EF or valvular disease. Thus, it is important to obtain a transthoracic echocardiogram. This helps to identify concomitant valvular disease, such as MR, that might necessitate an open operation, in which case the patient would be better served by mitral valve surgery with a concomitant Cox-Maze procedure. It might also identify a patient with reduced EF, and a more compelling argument might be made for surgical ablation to achieve sinus rhythm, given the mortality benefit of achieving rhythm control in this patient population.

Additionally, the patient may not have undergone evaluation for ischemia despite potential overlap of anginal equivalents, such as shortness of breath with exertion that accompanies their AF. A stress test is prudent, especially if the patient has a suspected tachycardia-induced cardiomyopathy, because numerically, coronary artery disease is still the more common cause of reduced EF. Revascularization in the setting of hemodynamically significant coronary artery disease is more imperative to treat than AF.

For patients with a history suggestive of lung disease, such as long-standing asthma or an extensive history of smoking, pulmonary function tests are warranted. Very low values of percent predicted lung volumes might steer the patient to the subxiphoid approach to obviate the need for single-lung ventilation.

Although not recommended for surgeons early in their experience with hybrid ablation, minimally invasive ablation can be done in the setting of prior heart surgery. Just like a redo sternotomy, gated chest CTA should be performed to ascertain mediastinal anatomy. Including the pelvic vessels can also be useful to plan for emergent initiation of cardiopulmonary bypass through groin cannulation in this setting.

Finally, at the time of operation, transesophageal echocardiography is mandatory to rule out clot in the left atrial appendage if management of the left atrial appendage is part of the operative plan.

Techniques

Groin vascular access with micropuncture sheaths should be obtained to facilitate initiation of cardiopulmonary bypass in the event of vascular or cardiac injury during manipulation of the heart and pulmonary vessels via scope-based approaches. A perfusionist and cardiopulmonary bypass machine should be in the room. Intraoperative transesophageal echocardiography is mandatory if the left atrial appendage will be manipulated to rule out intracavitary clot. Lung isolation is necessary for VATS-based approaches and can be achieved either by dual-lumen endotracheal intubation or bronchial blockers. Separate inflatable ROHO cushions are placed under each scapula and can be alternately inflated and deflated to elevate the operative side for either unilateral or bilateral VATS approaches. A sterile defibrillator pad is placed anteriorly, taking care to leave the site for VATS trocars uncovered, and a nonsterile pad can be placed on the back.

Subxiphoid Approach

Subxiphoid Convergent procedures can be achieved in a similar manner as a subxiphoid pericardial window. A vertical incision is made over the xiphoid process, which is then resected with a Sauerbruch rongeur. Dissection is carried down through the subcutaneous fat to the anterior surface of the inferior pericardium. This is sharply incised and extended to allow for insertion of the most commonly used instrument, the cannula, which is manufactured by AtriCure (Mason, OH) and resembles a mediastinoscope (Fig. 115.28). The left inferior and superior pulmonary veins can be identified as well as the pericardial reflection at the superior aspect of the posterior LA. Rightward deflection of the mediastinoscope reveals the right inferior vein. An epicardial radiofrequency ablator is then positioned along the posterior atrium defined by the previously described structures and sequentially moved from left to right, ablating as much of the posterior LA as is accessible. A multisensor esophageal temperature probe is used during the ablation to ensure no esophageal heating occurs in order to avoid the potentially fatal complication of atrial esophageal fistula formation. In between ablations, the field is irrigated with cold saline.

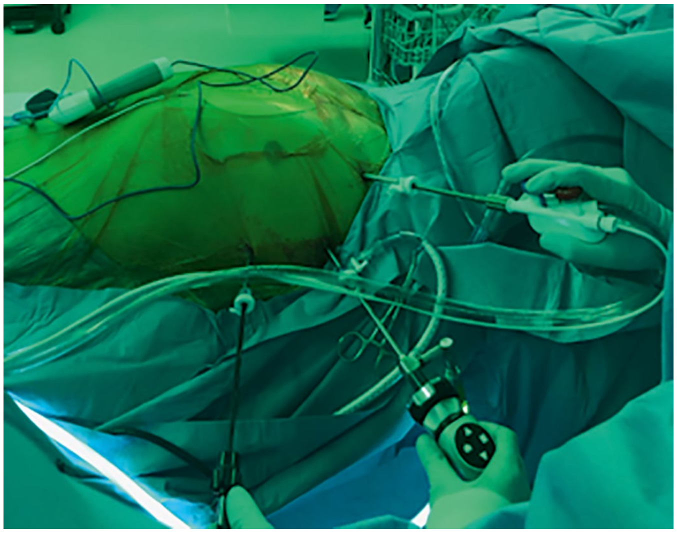

FIGURE 115.29 Left-side port placement. Note green ambient lighting to enhance contrast of red structures on video screen.

Video-Assisted Thoracoscopic Surgical Approach

Our institutional preference is for a left-sided VATS approach, although a bilateral approach is technically easier and safer. If anatomy precludes safe approach to the right pulmonary veins from the left side, a bilateral approach is used. Left-sided access is obtained first through the fifth intercostal space between the anterior and midaxillary line (Fig. 115.29). Insufflation of the left thorax aids in creating space to operate. Most patients tolerate an intrathoracic pressure of 8 mm Hg without hemodynamic compromise. Two additional trocars are placed approximately a handsbreadth away. The inferior trocar can be 12 mm in size or 5 mm in size. Dissection of the hilum is performed first, elevating the fat off the anterior surface of the left superior pulmonary vein and reflecting the phrenic nerve away from the planned site of pericardiotomy. A longitudinal extension is made, extending to the left main pulmonary artery superiorly and for several centimeters below the left inferior pulmonary vein inferiorly to create adequate space for the introduction of instruments into the posterior pericardium. The ligament of Marshall is divided. Dissection is carried through the transverse and oblique sinuses behind the SVC and inferior cava, respectively, to obtain access to the right-sided pericardium. In the typical bilateral approach, an articulated dissector with an illuminated tip is used to pass a rubber guide through the inferior trocar site around the left-side pulmonary veins (Fig. 115.30A). This guide is attached to the distal jaw of a bipolar radiofrequency ablation clamp and is used to position the clamp across the pulmonary veins (see Fig. 115.30B). A linear ablator is then passed through the oblique sinus and transverse sinus, in sequence, to create an ablation connecting the inferior

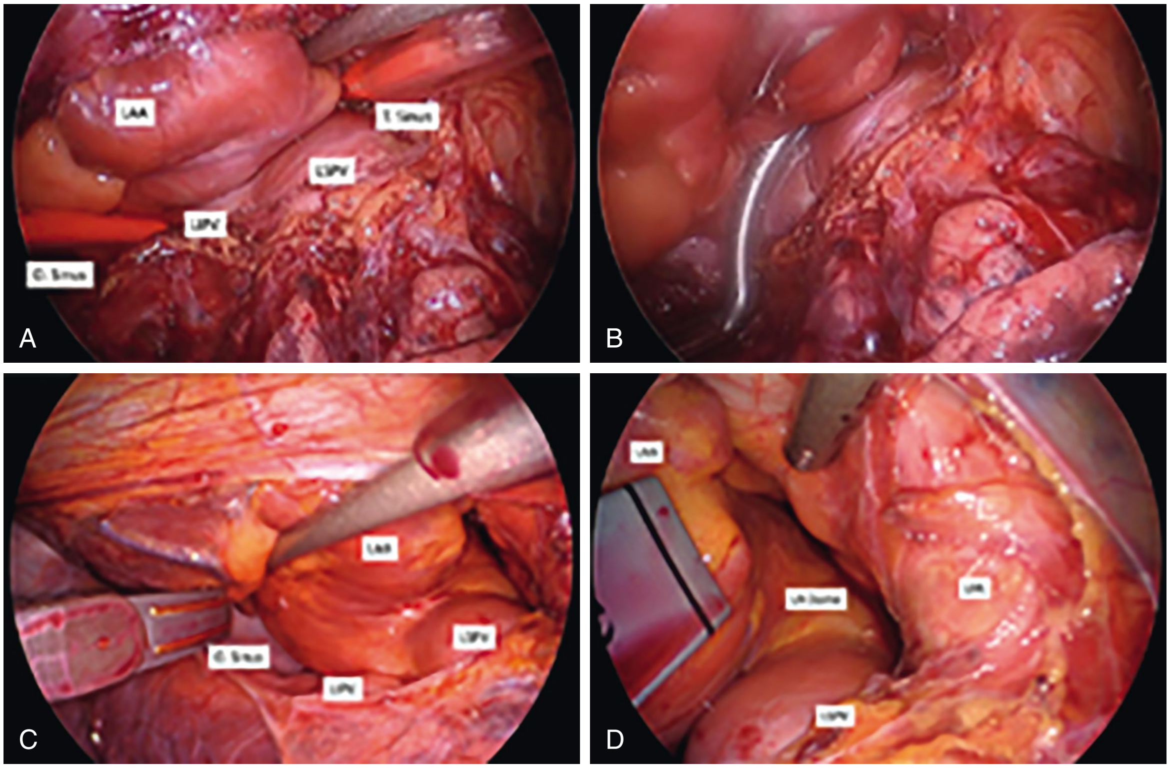

FIGURE 115.30 (A) Video-assisted thoracoscopic surgical approach. Red rubber guide seen coursing through oblique sinus, medial to left inferior pulmonary vein and left superior pulmonary vein, exiting through the transverse sinus. Left atrial appendage can be seen anterior to the hilum. (B) Clamp positioned around left pulmonary vein antrum aided by rubber clamp guide. (C) Ablator can be seen moving into oblique sinus. (D) Ablator approaching the right superior pulmonary vein through the transverse sinus over the dome of the left atrium.

right pulmonary vein to the inferior left pulmonary vein (floor line) and the right superior pulmonary vein to the left superior pulmonary vein (roof line) (see Fig. 115.30C–D). In a unilateral approach, the lighted dissector can be routed posterior to the IVC around the right-sided pulmonary veins laterally toward the right and subsequently back behind the SVC to pass the clamp guide around the right pulmonary vein antrum. In a bilateral approach, right-sided trocars are placed, and the already-dissected oblique and transverse sinuses allow for easy passage of the dissector after a right pericardiotomy anterior to the phrenic nerve. Before removing the ports on the left, a left atrial appendage clip can be applied through the inferior access incision.

Additional epicardial ablations can be performed if desired. Close collaboration with the electrophysiologist slated to do the follow-up endocardial ablation is crucial. Right-sided lesions can be performed, or additional left-sided lesions, such as a mitral isthmus line. Our practice is to perform posterior wall isolation alone so that incomplete ablations are not created as a nidus for atypical flutter.

Summary

AF prevalence outpaces many of the common cardiac diseases typically treated by the cardiothoracic surgeon. Although strictly percutaneous treatment, such as coronary artery disease, is in the purview of the cardiologist, minimally invasive techniques combined with catheter techniques in a hybrid surgical-catheter setting have been proven to be more effective than catheter ablation alone. Given the accumulating evidence of the clinical utility of ablation as first-line treatment for AF and its clear mortality benefit in patients with heart failure, it is imperative that cardiothoracic surgeons be familiar with and embrace hybrid ablation techniques so as to be active participants in team-based approaches to the treatment of AF, just as surgeons have become indispensable members of the heart valve team.

Multidisciplinary Approach
Challenges: Futility
Summary

INTRODUCTION AND BRIEF HISTORY

Extracorporeal membrane oxygenation (ECMO) provides mechanical support to patients with severe cardiorespiratory failure. It is an important resource that can offer an essential lifeline to salvage such critically ill patients by delivering respiratory and/or cardiac support when conventional therapies fail. ECMO is broadly categorized into three distinct modalities: venoarterial (VA), venovenous (VV), and venoarteriovenous (V-AV). VA ECMO is employed for cardiac support and in patients with decompensating cardiac failure and compromised end-organ perfusion, whereas VV ECMO is used for severe respiratory failure with intact cardiac function and provides gas exchange to correct severe hypoxemia and or hypercarbia. The less common V-AV ECMO serves as a hybrid model that is useful in dynamic clinical scenarios requiring flexible transitions between circulatory and respiratory support (Fig. 116.1).

Dr. John Gibbon developed the first successful heart-lung machine used for open heart surgery in 1953. However, it was not until the late 1960s that technology advanced enough for long-term extracorporeal support.[1] Dr. Robert Bartlett is often called the father of modern ECMO. In 1975, he used ECMO to save a newborn with meconium aspiration syndrome and resultant pulmonary hypertension. This landmark case demonstrated ECMO's potential, leading to its gradual adoption in neonatal and pediatric care units.[1]

The 1970s and 1980s saw ECMO primarily used in neonatal and pediatric settings. In 1972, Bartlett and associates first used cardiac ECMO successfully for 36 hours in a 2-year-old infant with cardiac failure after a Mustard procedure. The first successful prolonged extracorporeal support in an intensive care setting was reported by Dr. J.D. Hill in 1972, with a 24-year-old male supported for 75 hours after a motorcycle accident.[1]

Early studies did not show a mortality benefit of ECMO in adult patients, leading to a decline in initial enthusiasm for its use in adults. However, Dr. Robert Bartlett persisted in using ECMO for pediatric patients, achieving good outcomes. This persistence and success in the pediatric population allowed ECMO to continue as a viable therapy in that setting until technology and techniques improved, enabling broader applications and better outcomes in adults as well.

The 1990s and 2000s witnessed a significant expansion in the use of ECMO for adults. The H1N1 influenza pandemic in 2009 led to a sharp increase in ECMO application due to its effectiveness in managing severe respiratory failure associated with acute respiratory distress syndrome (ARDS). This success highlighted ECMO's utility in respiratory epidemics, leading to broader acceptance and usage.[1,2]

Technologic advancements have continued to expand ECMO's deployment, with the shift from roller pump to centrifugal pump technology, offering safer and more efficient circulation. Additionally, the move from silicone membrane to polymethylpentene

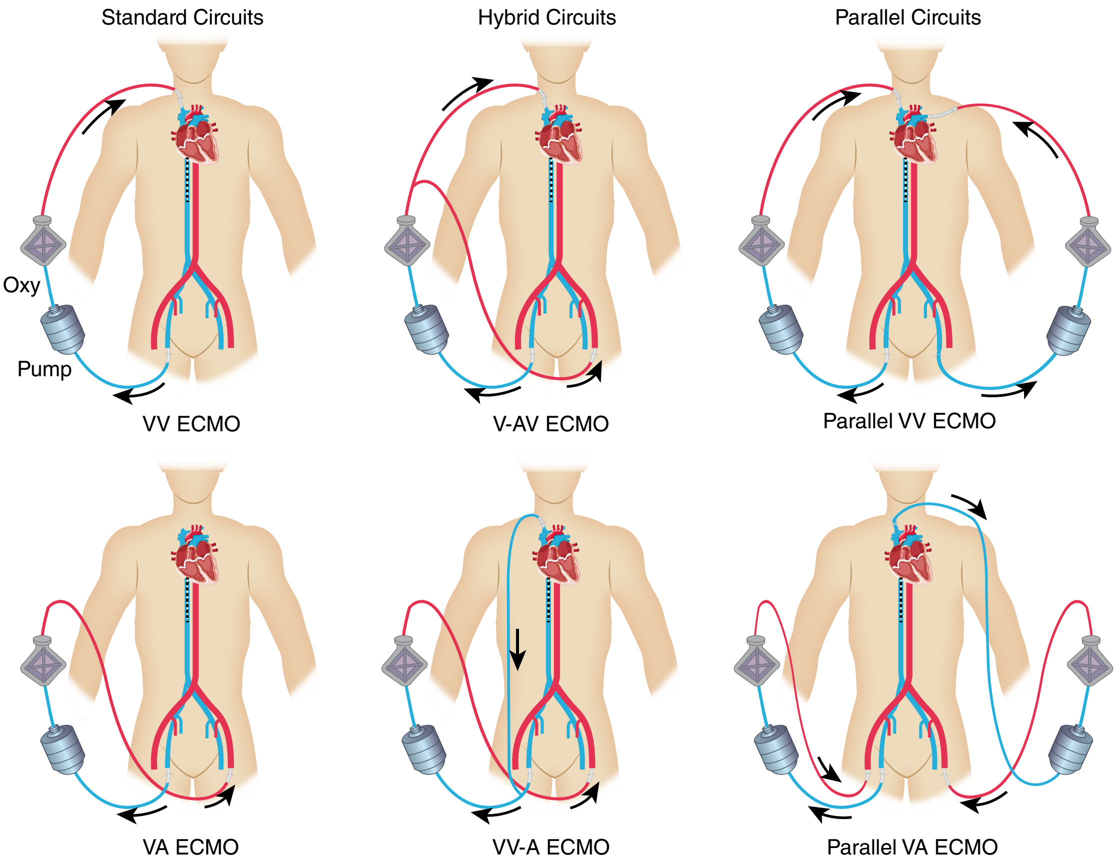

FIGURE 116.1 Various extracorporeal membrane oxygenation configurations including standard, hybrid, and parallel circuits. *Oxy*, Oxygen; *VA ECMO*, venoarterial extracorporeal membrane oxygenation; *V-AV ECMO*, venoarteriovenous extracorporeal membrane oxygenation; *VV ECMO*, venovenous extracorporeal membrane oxygenation; *VV-A ECMO*, venovenous-arterial extracorporeal membrane oxygenation. (From Shah A, Dave S, Goerlich CE, Kaczorowski DJ. Hybrid and parallel extracorporeal membrane oxygenation circuits. *JTCVS Tech*. 2021;8:77-85.)

oxygenators has allowed for better gas exchange and reduced blood trauma, further increasing the safety profile of ECMO support therapy (Fig. 116.2).

Ongoing ECMO research is focused on optimizing its efficacy and reducing risks associated with its insertion, circuit components, and prolonged patient cannulation. Its historical development from a niche surgical tool to a critical care mainstay underscores the importance of innovation and adaptation in medical technology.

ECMO cannulation techniques have also evolved over years from an open operative procedure to a percutaneous approach, especially in the setting of peripheral bedside cannulation. Peripheral ECMO cannulation often involves accessing vascular sites such as the jugular or femoral veins and femoral artery. Advances in technology enabled such peripheral cannulation to be safely and routinely performed at the bedside entirely percutaneously and outside of the operating room. This evolution has reduced complication rates and enabled faster initiation during emergency scenarios[3] (Fig. 116.3).

Conversely, central ECMO cannulation is generally reserved for intraoperative cases or postcardiotomy, offering advantages in specific patient populations but requiring intricate surgical skill. The approach for central cannulation can vary, with arterial cannulation done through a midline sternotomy for direct aortic/pulmonary artery cannulation or a right axillary cutdown for an axillary artery cannulation. Venous cannulation strategies can also vary in this setting with either a central venous cannulation or a femoral venous cannulation with central arterial return.[3–5]

Parallel ECMO circuits are employed when a single ECMO circuit fails to provide sufficient support, typically in cases of high cardiac output states or severe hypoxia. In these situations, adding an additional drainage and return cannula connected to a separate ECMO circuit can enhance oxygenation and perfusion. This technique can be particularly useful in septic patients or those with refractory hypoxia despite optimal management. Parallel circuits necessitate careful consideration of potential complications such as recirculation within and between circuits, thrombus formation, and maintaining adequate flow distribution to prevent hemodynamic instability.[5]

Using parallel ECMO circuits can effectively manage patients with severe cardiorespiratory failure when traditional configurations are insufficient. However, it is essential to monitor for complications such as recirculation and thrombus formation, ensuring adequate flow distribution. This advanced strategy should be reserved for specific clinical scenarios and managed by experienced ECMO teams.

Setting appropriate expectations for ECMO outcomes is crucial for both medical professionals and patient families. ECMO can serve as a bridge to recovery, providing vital hemodynamic support and end-organ perfusion while the patient recuperates from the primary underlying pathology. It may also act as a bridge to definitive surgery, such as a transplant or complex cardiac

procedure. ECMO can also be used as a bridge to decision or "nowhere," and initiated when a patient's prognosis is uncertain; this can raise significant ethical considerations later regarding the continuation of life-sustaining treatments when such a patient fails to recover and has no definitive surgical option. It is critical to understand that ECMO does not cure the underlying disease; rather, it offers a temporary reprieve from a life-threatening situation, allowing for more comprehensive management of the patient's condition.

RESPIRATORY FAILURE

VV ECMO is a specialized configuration of mechanical support for patients with severe respiratory failure. It is used primarily as a bridge to recovery or as a bridge to a definitive surgical intervention. This support system helps correct respiratory derangements including hypoxemia and/or hypercapnia that cannot be managed with conventional mechanical ventilation[2] (Fig. 116.4).

Indications

Extracorporeal Life Support Organization (ELSO) has published guidelines outlining specific criteria that patients should

FIGURE 116.5 Venovenous extracorporeal membrane oxygenation during the COVID pandemic. (Courtesy UMMC: VV ECMO during COVID.)

meet for VV ECMO consideration and include the following[1,6] (Fig. 116.5):

- Hypercapnia: Characterized by a CO_2 level >60 mm Hg with a pH <7.25, or an inability to maintain adequate ventilation with a plateau pressure (Pplat) ≤30 cm H_2O.[1]
- Severe hypoxemia: Defined by a partial pressure of oxygen (PaO_2)/fraction of inspired oxygen (FiO_2) ratio <50 mm Hg with an FiO_2 >80% for more than 3 hours, or a PaO_2/FiO_2 ratio <80 mm Hg with an FiO_2 >80% for more than 6 hours, despite optimized mechanical ventilation and attempts at rescue maneuvers such as prone positioning and neuromuscular blockade.[1]

Additional indications include:

- Refractory asthma: As a temporary support to reduce airway pressures and avoid barotrauma while allowing the lungs to heal.
- Bridge to lung transplantation: In patients with end-stage pulmonary disease who are candidates for lung transplantation.
- Protection from ventilator-induced lung injury (VILI): In cases where high ventilatory pressures are needed, which could exacerbate lung injury.

Contraindications

Although there are few absolute contraindications to VV ECMO, several relative contraindications must be considered in the context of each patients' potential reversibility of their underlying conditions and limitations on other life-sustaining treatments.[6] These include the following:

- Irreversible lung damage: Such as advanced fibrosis where recovery is not anticipated, and the patient is deemed not a candidate for lung transplantation.
- Severe multisystem organ failure: Not related to lung function, which does not support the expected quality of life postrecovery.
- Chronic conditions with poor prognosis: Including certain cancers or progressive neurologic disorders where the expected survival is limited.
- Advanced age and frailty: Although not absolute, age and general frailty are considered predictors of poorer outcomes and higher complication rates.

Cannulation Strategies

Cannulation for VV ECMO typically involves either the insertion of a single dual-lumen cannula or the placement of two separate cannulas for drainage and return. The type of dual-lumen cannula used can vary. For instance, Avalon (Getinge, Gothenburg, Sweden) and Crescent (Medtronic, Minneapolis, MN, USA) cannulas have bicaval drainage with return to the right atrium. In contrast, Protek (LivaNova, London, UK) and Spectrum (Spectrum Medical, Gloucestershire, UK) cannulas have drainage from the right atrium and return to the pulmonary artery, though these latter types are currently less commonly used.

Dual-lumen cannula placement often necessitates the patient being taken to the operating room for real-time procedural imaging with either transesophageal echocardiography or fluoroscopy to safely guide cannula insertion.[7] This concurrent intraprocedural imaging is necessary due to the exact cannula positioning required and the risk of iatrogenic right ventricle injury. The cannulation site is usually the internal jugular vein, with the proximal drainage positioned in the right atrium or right ventricle and the distal return positioned in the main pulmonary artery.

When two individual cannulas are used for peripheral cannulation, the drainage cannula is often placed in a femoral vein, whereas the return cannula can be inserted through either the femoral or internal jugular veins. In stable patients, peripheral cannulation is often preferred, with femoral drainage positioned at the level of the inferior cavoatrial junction and the internal jugular return cannula positioned at the superior cavoatrial junction. The most common site for the return cannula in this scenario is the right internal jugular vein, with a standard cannula insertion depth of approximately 15 cm, though this can be adjusted based on the patient's height.[5,8]

Ideally, the cannulas should be positioned 10 cm apart, with adjustments made to ensure there is minimal recirculation of the oxygenated blood back into the ECMO circuit. Recirculation diminishes effective oxygen delivery and is indicated by low peripheral oxygen saturation and unexpectedly high preoxygenator blood O_2 saturation. It is important to note that some degree of recirculation is always present in this configuration.[8]

If the patient is not deemed a candidate for femoral and internal jugular cannulation, a bilateral femoral cannulation approach can be used. When using this approach, there is a notable increased risk of possible recirculation (Fig. 116.6). The specific nuances of this approach include the following:

- Right femoral return cannula: The shorter course of the venous system on the right side provides a few additional centimeters to ensure proper placement and distance from the drainage cannula. A single-stage venous cannula should be used as the return cannula as its side holes are located only within the first 5 cm of the tip. This design focuses the flow at the tip, maximizing the distance between the side holes on the return and drainage cannulas, thereby optimizing the effectiveness of the ECMO circuit.

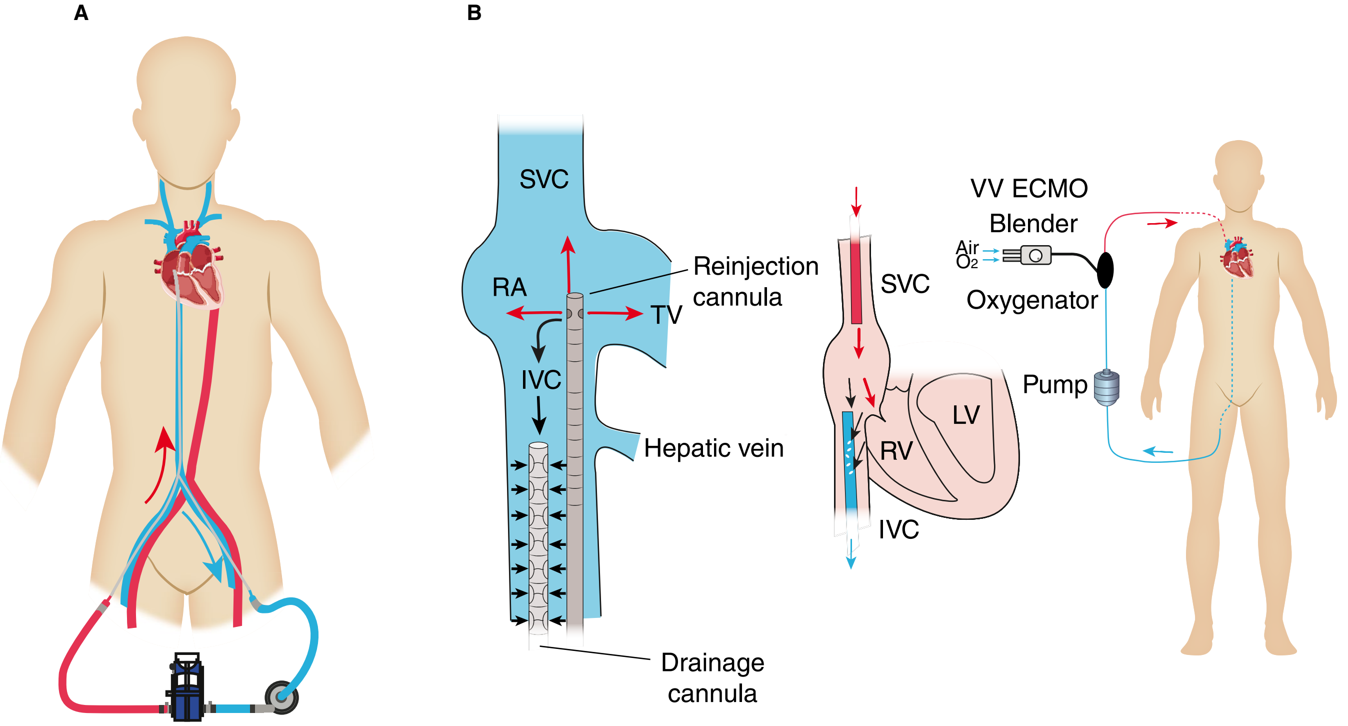

FIGURE 116.6 (A–B) Venovenous extracorporeal membrane oxygenation recirculation. *IVC,* Inferior vena cava; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava; *TV,* tricuspid valve; *VV ECMO*, venovenous extracorporeal membrane oxygenation (Courtesy UMMC: recirculation.)

- Left femoral drainage cannula: The drainage cannula should be placed in the left-sided femoral vein given the increased distance from the insertion site to the inferior vena cava (IVC). The position of this cannula in relation to the outflow of the return cannula should ideally be ~5 cm apart. This positioning would minimize the risk of recirculation; however, this must be balanced with the ECMO circuit flow as position is associated with an increased risk drainage obstruction. Even at distances larger than 10 cm, recirculation can still occur, and it is important to frequently monitor the patient's ECMO circuit and pump gases.

In both cannulation techniques, a bedside transthoracic echocardiogram showing the IVC and the right atrial junction via subxiphoid view can be used to visualize the wire and ensure proper initial positioning of the cannula. If peripheral access is impractical, central access may be considered as an alternative.

General Management

Once VV ECMO is initiated, management involves a multidisciplinary team including ECMO surgeons, intensivists, advanced practice providers, nurses, respiratory therapists, perfusionists, and ECMO specialists. This team is frequently supported by consultations from specialty services such as Infectious Disease, Pulmonary Medicine, Nutrition, Occupational and Physical Therapy, and Palliative Care.[2]

The primary goal of VV ECMO is to allow the lungs to rest while the ECMO circuit performs the gas exchange functions. Ventilator settings are adjusted to ensure minimal lung strain, typically with a plateau pressure <25 cm H_2O, a driving pressure <15 cm H_2O, and a tidal volume of 4 to 6 cc/kg of predicted body weight. Various modes of ventilation can be used to maintain these lung rest settings, including volume control and pressure control ventilation (PCV), with PCV settings often at a plateau pressure of 20 cm H_2O, a positive end-expiratory pressure (PEEP) of 10 cm H_2O, a respiratory rate of 10, and an FiO_2 of 40%.[2,9,10]

Persistent hypoxia post-ECMO initiation necessitates a systematic assessment of both the patient and the ECMO circuit. This includes ensuring the oxygenator is functioning correctly and checking for recirculation. Management strategies for recirculation might involve repositioning the cannulas to increase the distance between the drainage and return lines, reducing the pump speed, or adding an additional drainage cannula.

For patients exhibiting a hyperdynamic state with ECMO flow rates <60% of total cardiac output, resulting in persistent hypoxemia and an SaO_2 <90%, initial strategies include increasing pump flow up to the maximum safe revolutions per minute (RPM). If higher flow rates are required, introducing a second drainage cannula or switching to central cannulation may be considered. Medications such as β-blockers can help reduce the cardiac output and allow for more of the total cardiac output to be captured by the ECMO circuit.[10]

In cases that remain refractory, efforts should focus on maximizing oxygen delivery and minimizing oxygen demand. Techniques include sedation, paralysis, diuresis, cooling, and maintaining hemoglobin levels above 9 to 10 g/dL to enhance oxygen-carrying capacity.

For carbon dioxide and hypercarbia management, the ECMO circuit's sweep gas should be adjusted to maintain a PCO_2 between 35 and 45 mm Hg, targeting a pH between 7.35 and 7.45. If standard sweep gas rates are insufficient, consider using an additional blender or oxygenator. Proper ventilator management is also crucial to complement ECMO support as optimizing vent settings minimize full dependence on ECMO for gas exchange.[2,10]

When troubleshooting low flow or chugging (circuit flow interruptions due to negative pressure or air entrainment), ensure adequate volume status, check cannula positioning, and inspect for any mechanical obstructions or kinks in the tubing. Additionally, verify that there are no issues with the pump or oxygenator that could be causing reduced flow (Fig. 116.7).

Anticoagulation Management

Routine anticoagulation with heparin is recommended with specific partial thromboplastin time (PTT) goal and anti-Xa goals that are institution specific. If there is a significant risk of bleeding, anticoagulation may be withheld, as VV ECMO can often be operated for extended periods without it. However, it is important to understand that there is a notable thrombotic event risk if anticoagulation is not used. Maintaining a flow above 4 L/min and diligent circuit evaluations for thrombotic formation can help mitigate these risks. In cases of suspected or confirmed heparin-induced thrombocytopenia (HIT), patients should be transitioned to alternative anti-Xa anticoagulants such as argatroban or bivalirudin.[11]

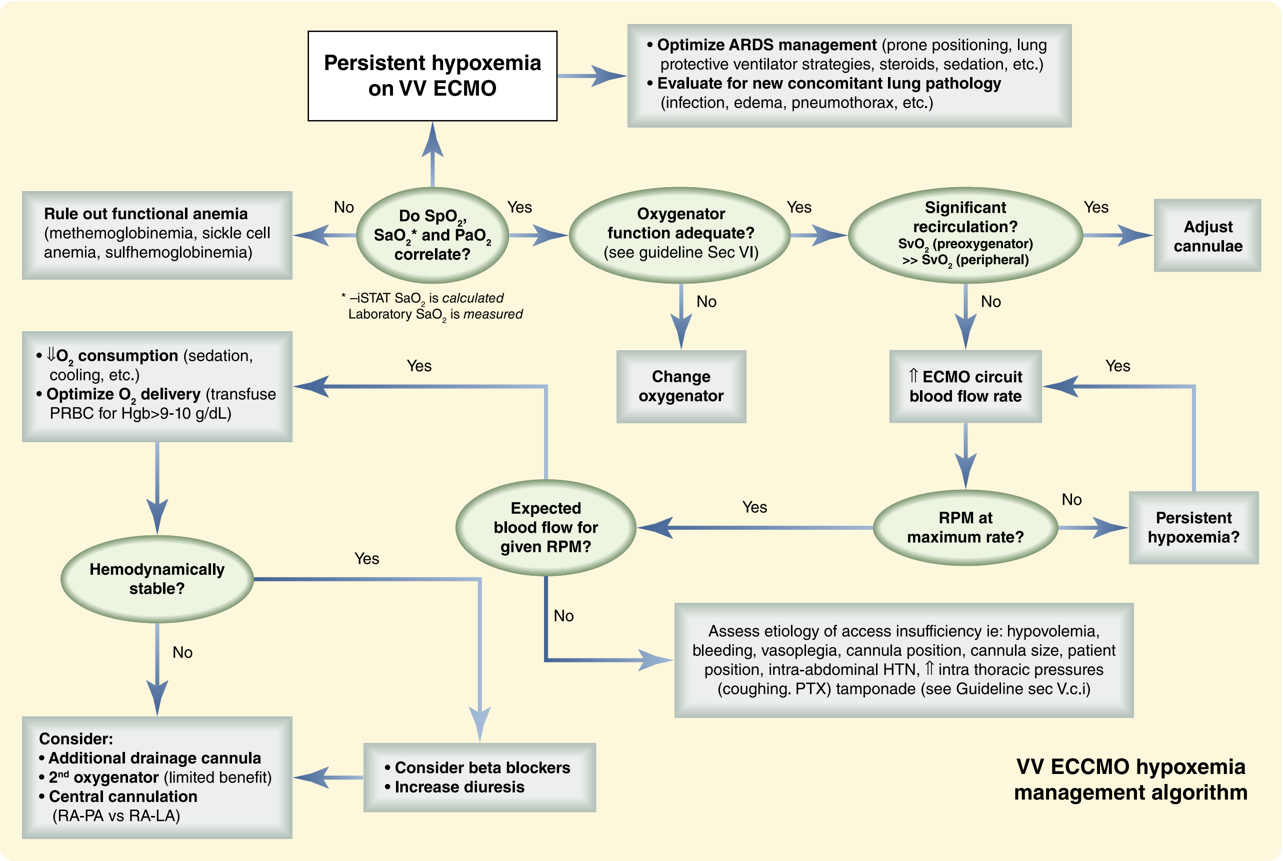
VV ECMO in the Context of Standard Acute Respiratory Distress Syndrome Management

Steroids: The use of steroids in ARDS management can be beneficial in reducing inflammation and improving oxygenation. In patients on VV ECMO, steroids are often continued as part of the standard ARDS treatment protocol to help modulate the inflammatory response and improve recovery. Various steroid dosing strategies have been used in this patient population and include the DEXA-ARDS and Meduri protocols.[2,12,13]

Prone positioning: Prone positioning is a well-established strategy to improve oxygenation in ARDS patients as it may improve ventilation-perfusing mismatch and aids in secretion clearance. For patients on VV ECMO, prone positioning can still be performed, although it requires careful coordination and monitoring to avoid complications related to the cannulas and ECMO circuit. The improved oxygenation from prone positioning can complement the oxygenation support provided by VV ECMO.[2,12,13]

Volume management: Managing fluid balance is critical in ARDS patients to avoid fluid overload, which can worsen pulmonary edema and impair gas exchange. For patients on VV ECMO, precise volume management is essential to maintain optimal circuit function and prevent complications such as pulmonary edema or right heart strain. Volume management can be uniquely challenging in this patient population. The providers must balance volume removal as treatment for ARDs and pulmonary function with maintenance of adequate intravascular volume to ensure sustained ECMO flows and end-organ perfusion.[2,12,13]

Early tracheostomy: Early tracheostomy can benefit ARDS patients by facilitating weaning from mechanical ventilation, improving patient comfort, and enabling patients to be awake and participative. In patients on VV ECMO, early tracheostomy



Persistent hypoxemia on VV ECMO
• Optimize ARDS management (prone positioning, lung protective ventilator strategies, steroids, sedation, etc.)
• Evaluate for new concomitant lung pathology (infection, edema, pneumothorax, etc.)
Rule out functional anemia (methemoglobinemia, sickle cell anemia, sulfhemoglobinemia)
No
Do SpO2, SaO2* and PaO2 correlate?
Yes
* –iSTAT SaO2 is calculated
Laboratory SaO2 is measured
Oxygenator function adequate? (see guideline Sec VI)
Yes
Significant recirculation? SvO2 (preoxygenator) >> SvO2 (peripheral)
Yes
Adjust cannulae
No
Change oxygenator
No
⇑ ECMO circuit blood flow rate
Yes
• ⇓O2 consumption (sedation, cooling, etc.)
• Optimize O2 delivery (transfuse PRBC for Hgb>9-10 g/dL)
Yes
Expected blood flow for given RPM?
Yes
RPM at maximum rate?
No
Persistent hypoxemia?
Hemodynamically stable?
Yes
No
No
Assess etiology of access insufficiency ie: hypovolemia, bleeding, vasoplegia, cannula position, cannula size, patient position, intra-abdominal HTN, ⇑ intra thoracic pressures (coughing. PTX) tamponade (see Guideline sec V.c.i)
Consider:
• Additional drainage cannula
• 2nd oxygenator (limited benefit)
• Central cannulation (RA-PA vs RA-LA)
• Consider beta blockers
• Increase diuresis
VV ECCMO hypoxemia management algorithm

can also aid in managing secretions, reducing sedation requirements, and accelerating lung recovery, allowing providers to take advantage of awake ECMO care.[14]

Vasoactive support: Vasoactive medications and infusions may be necessary to support blood pressure and cardiac output in hypotensive ARDS patients, especially those with septic shock and other etiologies of hemodynamic instability. For patients on VV ECMO, careful titration of vasoactive agents is crucial to ensure adequate perfusion and oxygen delivery while maintaining stable ECMO circuit function.

By integrating these standard ARDS management strategies with the specialized support provided by VV ECMO, clinicians can optimize care and potentially improve outcomes for patients with severe respiratory failure.

Specific Sedation Goals in ECMO Management

Minimize sedation: The primary goal is to minimize sedation to allow patients to be awake and interactive. This involves administering the lowest effective doses of sedatives to ensure patient comfort while maintaining consciousness.[15]

Facilitate mobility and ambulation: Sedation reduction helps patients participate in physical therapy and ambulation. Increased interactivity and mobility can significantly improve outcomes by preventing muscle atrophy, enhancing lung function through spontaneous breathing, and reducing the risk of complications such as deep vein thrombosis (DVT) and pressure ulcers.[15,16]

Maintaining physical conditioning through ambulation is especially crucial for pretransplant patients. Such pretransplant conditioning is associated with improving transplant outcomes and recovery. Ambulation also provides significant psychological benefits by empowering patients and enhancing their overall well-being.

Effective ambulation on ECMO requires meticulous planning and coordination among the healthcare team, along with the use of specialized mobile ECMO equipment. Continuous monitoring of vital signs and ECMO circuit function is essential to ensure patient safety. By promoting mobility, healthcare providers can optimize physical and psychological health, leading to better overall outcomes for patients on ECMO.

Enhance communication: Keeping patients awake enables better communication with the healthcare team, which is crucial for assessing their needs, managing pain effectively, and understanding the patient's goal of care. This also helps in monitoring neurologic status and early detection of complications.

Weaning From VV ECMO

Successful weaning from VV ECMO is heavily dependent on the etiology of the respiratory disease and the patient's overall goals of care. As the VV ECMO and mechanical ventilation are often used together, there is an important patient-specific balance between the two modalities that can facilitate an ideal outcome. In considering weaning of mechanical support, many patients are decannulated from VV ECMO before ventilator liberation. There is still a subset of patients who are first weaned off ventilator support, and only later decannulated from VV ECMO without further mechanical ventilation. Identifying these patients is often challenging, but it affords the potential for improved patient nutrition, participation in rehabilitation, optimal lung rest, and reduced ventilator-associated infections.[10,17]

Weaning protocols vary between institutions. A preferred strategy involves weaning the sweep gas flow rate rather than the sweep gas FiO_2 or total flow. Another method is to slowly wean the FiO_2 concentration of the circuit, which is set at 100% initially, or to slowly decrease the circuit flow rate.[2,17,18] However, decreasing the ECMO flow rate can increase the risk of thrombotic events as higher flow rates help mitigate thrombus formation throughout the circuit.

Weaning of Sweep Gas Flow

- Gradual reduction: The sweep gas flow rate, which controls the removal of CO_2 from the blood, is titrated to a patient's PCO_2 level. As the patient's native lung function improves, the sweep is gradually reduced until the patient's lungs can manage CO_2 clearance without ECMO support. When the sweep is turned off, the patient is no longer receiving ECMO support and is simply recirculating the blood in the ECMO circuit.[10]
- A patient may or may not be on mechanical ventilation when starting a recirculation trial. For patients who are still mechanically ventilated, increasing ventilator support while staying within reasonable parameters is often used to reduce time on ECMO and allow for an earlier decannulation.
- Arterial blood gases (ABGs) are closely monitored during this process to ensure that CO_2 levels remain within an acceptable range. An increase in the patient's respiratory drive or signs of respiratory acidosis may indicate the need to slow the weaning process or an increase in mechanical ventilation support.[10]

Acceptable Ventilator Parameters

- Lung recovery: Before considering decannulation, the patient should demonstrate adequate lung recovery. Acceptable ventilator parameters typically include a low FiO_2, often less than 40%, and a PEEP of 8 to 10 cm H_2O with a peak pressure no greater than 20 to 25 cm H_2O. In some clinical settings, it is reasonable to extubate patients before weaning VV ECMO support.
- Stable blood gases: ABGs should show adequate oxygenation ($PaO_2 > 60$ mm Hg on low FiO_2) and ventilation ($PaCO_2$ within normal limits) on minimal ventilator settings. The patient should also be capable of maintaining spontaneous breathing efforts without significant support.

Clinical Stability

- The patient should be hemodynamically stable, with minimal or no need for vasoactive medications. Signs of clinical improvement, such as decreased pulmonary infiltrates on chest imaging and improved lung compliance, should also be evident.

Decannulation Procedure

Preparation: Decannulation is a planned procedure that requires careful preparation. The patient should be in a controlled environment, such as the intensive care unit (ICU) or operating room, with all necessary personnel and equipment on hand. Coagulation labs should be evaluated and corrected before decannulation, and blood products should be readily available at the bedside if needed. It is important to have a clear goals-of-care discussion with the family and the patient to determine whether the patient is a recannulation candidate before decannulation.

Cannula removal: It is crucial to set up the field appropriately before attempting decannulation. Begin by removing all but one suture securing the cannula. Place a large 0 Prolene purse-string suture around each cannula insertion site. For patients who still have their oxygenator in line with their ECMO circuit, return the blood from the circuit to the patient before clamping the cannulas. This step should be guided by the patient's ventilator status, renal function, right ventricular (RV) function, and volume management. For instance, avoid returning the entire circuit volume to a patient who is on continuous renal replacement therapy (CRRT) with borderline ventilator settings or someone with moderate RV dysfunction who may not tolerate a rapid 1-L blood bolus well.

The procedure typically starts with the removal of the drainage cannula, followed by the return cannula. When removing the cannula, it is important to do so in one swift, controlled motion to minimize blood loss. Allow for back-bleeding before tying down the purse-string suture to ensure any clot around the cannula is removed. This is followed by applying occlusive pressure to the site.

Hemostasis and monitoring: After removing the cannulas, achieving hemostasis is crucial to prevent bleeding complications. Continuous monitoring of vital signs, including heart rate, blood pressure, and oxygen saturation, is essential during and after the procedure to detect any immediate complications.

Postdecannulation care: The patient is closely observed for signs of respiratory distress, hemodynamic instability, or bleeding. Frequent ABGs and chest imaging may be performed to ensure that the patient maintains adequate gas exchange and lung function without ECMO support. A venous duplex of the lower extremities should be performed 24 hours following decannulation to evaluate for any cannulation-associated DVTs. It is common to identify such DVTs, which should be treated in the same fashion as other DVTs with anticoagulation and outpatient follow-up.[19] Duration of anticoagulation should also follow routine DVT treatment guidelines.

CARDIAC FAILURE

VA ECMO is a specialized configuration of mechanical support for patients with severe cardiac failure. It is used primarily as a bridge to recovery or as a bridge to a definitive surgical intervention such as transplant, left ventricular assist device (LVAD), revascularization, or structural repair. This support system helps correct end-organ malperfusion associated with cardiac failure that cannot be managed with standard conventional medical therapy[1,20–23] (Fig. 116.8).

Indications for ECMO in Cardiac Failure

- ***Postcardiotomy cardiac support:*** ECMO is also indicated postoperatively if the patient fails to wean off cardiopulmonary bypass due to myocardial stunning or if there is an unexpected postoperative deterioration in cardiac function.[3,4,20,24]
- ***Refractory cardiogenic shock:*** ECMO is indicated for patients who do not respond to conventional medical therapies including inotropic support or less extensive mechanical support such as Impella or intraaortic balloon pump (IABP).[20,21]
- ***Pulmonary embolism:*** In massive pulmonary embolism where there is significant cardiac compromise in the setting of obstructive shock, VA ECMO can support both the right-sided heart and provide oxygenation, allowing for interventions to address the embolism or for pharmacologic therapies to take effect.[25–27]
- ***Toxic myocarditis:*** In cases of severe myocarditis resulting from infections or toxic exposures where cardiac function is severely compromised, VA ECMO can provide support while the myocardium recovers or until definitive treatment can be administered.[28]

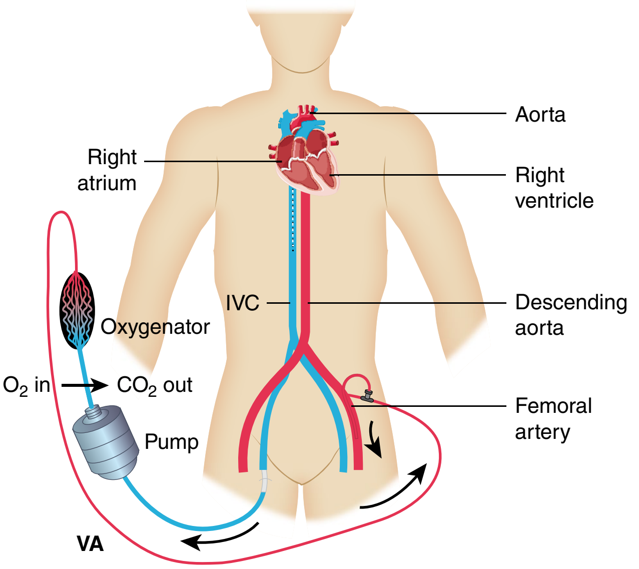

FIGURE 116.8 Venoarterial *(VA)* extracorporeal membrane oxygenation cannulation configuration. *IVC,* Inferior vena cava. (From Shah A, Dave S, Goerlich CE, Kaczorowski DJ. Hybrid and parallel extracorporeal membrane oxygenation circuits. *JTCVS Tech.* 2021;8:77-85.)

- ***Acute myocardial infarction (AMI):*** VA ECMO can be lifesaving in cases of cardiogenic shock post-AMI, especially when there is a mechanical complication like ventricular septal rupture, acute mitral regurgitation due to papillary muscle rupture, or RV failure.[20,29]
- ***Support during high-risk percutaneous coronary interventions (PCIs):*** For patients at high risk of hemodynamic instability during procedures such as PCI, ECMO can provide necessary circulatory support.[30]
- ***Refractory ventricular arrhythmias:*** In cases of severe ventricular arrhythmias that are refractory to medical treatment and pose a risk of hemodynamic instability and end-organ malperfusion, VA ECMO can stabilize hemodynamics and provide a bridge to more definitive therapies like catheter ablation or sympathectomy.[31]
- ***Cardiac arrest:*** Extracorporeal cardiopulmonary resuscitation (ECPR) is used when conventional CPR fails in the event of cardiac arrest, especially in settings where the likelihood of rapid recovery with conventional measures is low. This approach is particularly considered in potentially reversible situations or situations where etiology is not entirely known.[24]
- ***Bridge to decision/therapy:*** ECMO serves as a bridge to decision, giving clinicians time to evaluate the viability of further invasive therapies or transplantation. It can also be a bridge to therapy, maintaining patient stability until long-term solutions such as a ventricular assist device (VAD) or heart transplant can be implemented.[32]

Contraindications for ECMO in Cardiac Failure

- ***Irreversible cardiac conditions:*** ECMO is not recommended for patients with end-stage heart disease where there is no definitive therapy or when they are not candidates for transplantation or LVAD. In this scenario, recovery is highly unlikely and continued ECMO support will be futile.

- ***Severe coagulopathies or active hemorrhage:*** Active bleeding or severe coagulopathies that cannot be medically corrected and managed are major contraindications due to the high risk of bleeding complications associated with ECMO. Hypovolemic shock in the setting of uncontrolled bleeding is considered a relative contraindication for VA ECMO cannulation.
- ***Terminal illnesses and severe comorbidities:*** Terminal illnesses that limit life expectancy and severe comorbid conditions that do not support the overall goals of care may also preclude the use of ECMO.
- ***Advanced age:*** Although not an absolute contraindication, the risks and benefits of ECMO need careful consideration in elderly patients or frail patients, especially those with diminished physiologic reserves.
- ***Prolonged cardiac arrest:*** In the setting of ECPR, patients with prolonged downtimes greater than an hour or have an unwitnessed out of hospital arrest with unknown downtimes are often not candidates for VA ECMO cannulation given their overall poor prognosis.

Cannulation Strategies

- ***Peripheral cannulation strategy:*** An increasingly used technique whose insertion sites include the common femoral vein and artery for VA ECMO. This approach allows for rapid cannula placement at the bedside with the need for an operating room or interventional procedural suite. However, this femoral artery cannulation strategy provides retrograde flow and can be associated with vascular complications and limb ischemia. To mitigate these risks, a wire reinforced distal perfusion catheter is placed antegrade in the superficial femoral artery to provide perfusion to the arterially cannulated limb[3,33,34] (Fig. 116.9).
- ***Central cannulation strategy:*** Typically employed postcardiotomy during cardiac surgery cases or in the setting of severe peripheral vascular disease, central cannulation provides antegrade flow and involves the direct arterial cannula of the aorta through a midline sternotomy.[3,4,6] It is also possible to perform central cannulation through the right axillary artery following an axillary cutdown, but note that special consideration needs to be taken. This includes ensuring flow down the cannulated arm by using a vascular chimney graft or placement of a distal perfusing catheter down the arm. It is also important to consider the distance the cannula tip is from the right vertebral and carotid arteries as the cannula can obstruct carotid flow if advanced too far.
- ***Other cannulation strategy:*** Combining central and peripheral techniques, such as central innominate/aortic cannulation and femoral venous cannulation, can optimize support in complex cardiac conditions, allowing customization of flow dynamics according to patient needs. Other sites of cannulation include peripheral axillary cannulation through a surgical axillary cutdown and femoral venous cannulation. It is important to note these alternative strategies may require the addition of a distal perfusion catheter to provide perfusion to the corresponding arm.[3,8,16] These alternative forms allow a clinician to take advantage of central antegrade cannulation while mitigating the associated infection risk of standard central cannulation through a midline sternotomy.

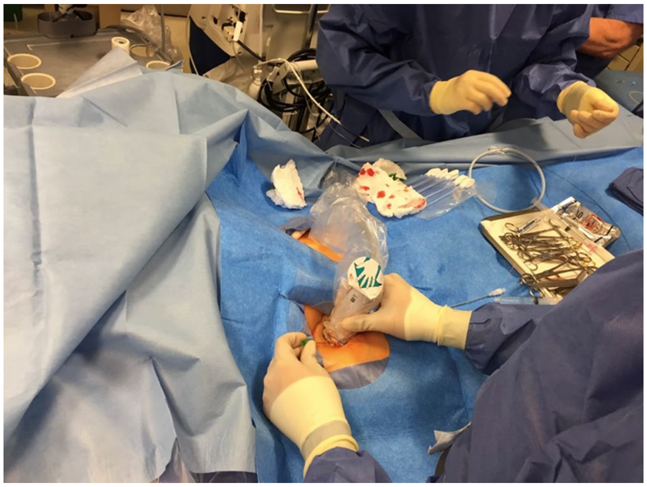

FIGURE 116.9 Ultrasound-guided placement of the distal perfusion catheter. (Courtesy UMMC: distal perfusion placement.)

Anticoagulation Considerations

The primary goal is to prevent clot formation in the ECMO circuit and cannulas that could potentially embolize or impede oxygenator function while minimizing the risk of bleeding. This is typically managed with continuous infusion of anticoagulants like unfractionated heparin. Regular monitoring of anticoagulation levels using tests such as activated clotting time (ACT), anti-Xa levels, or activated partial thromboplastin time (aPTT) is crucial.[20,35] Given the significant risk of systemic emboli and embolic stroke associated with VA ECMO, these anticoagulation goals are often higher when compared with VV ECMO; however, the policy is also institution specific.

Strategies must be in place to manage and quickly address any bleeding complications, which are significant risks given the systemic anticoagulation necessary for ECMO. Specific goals, however, should be tailored to individual patients and their specific clinical setting. A general approach to anticoagulation management includes maintaining a PTT goal of 60 to 80 seconds for patients without significant bleeding risk. For patients with pulmonary emboli or other conditions requiring higher anticoagulation, a higher PTT target is clinically indicated. If there is a concern for a major bleeding event, anticoagulation can be held, or a lower PTT goal can be used. In these scenarios, the risk of an embolic event must be weighed against the risk of a major bleeding event. Adjustments are made based on clinical response, bleeding events, and changes in patient condition, such as infection, hemolysis, or organ function.

Volume Management on VA ECMO

Volume management is crucial in VA ECMO settings as many patients are volume overloaded before cannulation and are in a state of decompensated heart failure. Effective strategies for volume removal include the following[20,21,36]:

- ***Diuretics:*** Diuretics are commonly used to manage fluid balance by promoting urine output, helping to control volume status in patients whose renal function is still intact.
- ***Hemoconcentrator:*** A hemoconcentrator can be integrated into the ECMO circuit, allowing for the removal of excess fluid directly from the blood, allowing for precise control of fluid balance without significantly impacting electrolyte or drug levels. This is especially useful in the setting where rapid removal of volume is necessary, but this is not recommended as a long-term volume management strategy as there can be an increased risk of hemolysis.

- ***CRRT:*** This facilitates continuous removal of fluid, electrolyte clearance, and acid-base management in the setting of impaired renal function, allowing for gentle and consistent fluid balance correction, which is especially beneficial in hemodynamically unstable patients. CRRT can be connected to the ECMO circuit either by integrating it into the existing lines or through separate vascular access. Integration into the ECMO circuit reduces the need for additional vascular access, minimizing infection risks and vascular complications. However, it is important to note that there is risk in using this method as CRRT flow will be dependent on and influenced by your ECMO flows, and if integrated incorrectly (prepump) there is a risk of catastrophic air entrainment. This could cause the circuit to experience an airlock leading to circuit failure and emergent circuit exchange.
- ***Slow continuous ultrafiltration (SCUF):*** SCUF provides continuous fluid removal at a slower rate than conventional hemodialysis and is a specific form of CRRT that focuses on volume removal. In patients who have intact renal function, the addition of SCUF directly into the ECMO circuit can aid in the removal of volume where rapid volume removal is required.

Fluid removal must be carefully balanced against the patient's intravascular volume, cardiac output, end-organ perfusion requirements, and ECMO flow rate. Overaggressive fluid removal can lead to hypovolemia, decreased cardiac output, potential collapse of the circulatory system, and ECMO flow complications. Regular monitoring of fluid status using clinical examination, hemodynamic monitoring such as central venous pressure, and input-output calculations is crucial for proper volume management. Advanced monitoring techniques such as echocardiography can assist in assessing volume status and cardiac function even while on ECMO support.

Management of Inotropic and Vasoactive Support

When managing patients on VA ECMO, the titration of vasoactive infusions including inotropes, vasopressors, and antihypertensives is critical to ensure adequate cardiac pulsatility, systemic perfusion, and stable ECMO flows. The following is a detailed list of commonly used inotropes and vasopressors, including their mechanisms, indications, and considerations specific to the ECMO setting.[1,3,10,16,21,23]

Inotropes on VA ECMO

Inotropes are primarily used to improve cardiac contractility and ensure adequate cardiac pulsatility, which is crucial for patients with reduced myocardial function on ECMO. Inotropes on ECMO should primarily be used to maintain pulsatility and emptying of the left ventricle. If there is adequate pulsatility without the use of inotropes, it is preferable to allow the heart to "rest" and avoid the stress associated with increased adrenergic drive. As inotropes increase myocardial oxygen demand, their use should be minimized, especially after events such as cardiac arrest or myocardial infarction, to avoid further strain on the heart while on ECMO.

Dobutamine.

- Mechanism: β_1-adrenergic agonist that increases myocardial contractility and stroke volume.
- Indications: Used to enhance cardiac output and vasodilation in patients with low cardiac function without significantly increasing heart rate.
- ECMO considerations: Useful in reducing ventricular afterload while increasing overall cardiac function and contractility; monitor for tachyarrhythmias and increased myocardial oxygen consumption.

Milrinone.

- Mechanism: Phosphodiesterase-3 inhibitor that increases cardiac contractility and produces vasodilation.
- Indications: Beneficial for RV failure and pulmonary hypertension; often used when β-adrenergic effects are undesirable.
- ECMO considerations: Can lower systemic vascular resistance; useful in weaning from ECMO as it improves diastolic relaxation and decreases pulmonary vascular resistance. Mainstay for patients with systemic vascular resistance reserve and signs of RV failure.

Epinephrine.

- Mechanism: Potent α- and β-adrenergic agonist that increases myocardial contractility, heart rate, and systemic vascular resistance.
- Indications: Used in severe cardiogenic shock when stronger inotropic support is needed to maintain pulsatility.
- ECMO considerations: Results in increased myocardial oxygen demand and arrhythmogenicity.

In the setting of VA ECMO, the use of inotropic support focuses on ensuring pulsatility and the opening of the aortic valve. End-organ perfusion and RV decompression can be accomplished with VA ECMO support alone. However, if pulsatility is lost, there is a significant increased risk of pulmonary congestion leading to respiratory failure and catastrophic thrombus formation within the aortic root and left ventricular (LV) cavity due to LV distention and left atrial hypertension. Additionally, LV distention and elevated LV end-diastolic pressure reduce coronary perfusion pressure, thereby decreasing myocardial oxygen delivery, which can be detrimental to the heart's function.

Inhaled Agents on VA ECMO

Inhaled vasodilators are used primarily to target pulmonary vasculature, reducing pulmonary arterial pressure and improving right heart function without causing significant systemic hypotension.

Nitric oxide.

- Mechanism: Inhaled nitric oxide (NO) is a selective pulmonary vasodilator that works by relaxing vascular smooth muscle. It specifically reduces pulmonary artery pressure and pulmonary vascular resistance, thereby decreasing RV afterload.
- Indications: Used for patients with pulmonary hypertension or RV dysfunction; also beneficial in improving oxygenation in hypoxic respiratory failure.
- ECMO considerations: Inhaled NO is effective during ECMO because it does not affect systemic vascular resistance. It is particularly useful in managing patients with severe pulmonary hypertension on ECMO, helping to optimize RV function and facilitate weaning from ECMO.

Epoprostenol (prostacyclin, PGI2).

- Mechanism: Epoprostenol is a potent vasodilator with antithrombotic properties. When inhaled, it primarily acts on the pulmonary circulation to decrease pulmonary arterial pressure with some systemic vasodilation in select patients.
- Indications: Indicated for pulmonary hypertension, especially when systemic effects of oral or intravenous vasodilators are undesirable. It helps in reducing RV afterload and improving cardiac output.
- ECMO considerations: Its use during ECMO can aid in reducing the pulmonary vascular resistance more selectively compared with systemic administration.

Iloprost (inhaled).

- Mechanism: Similar to epoprostenol but longer acting, iloprost is a synthetic prostacyclin that causes vasodilation of the pulmonary arterial bed.
- Indications: Used for the treatment of pulmonary arterial hypertension and can be useful in managing postoperative pulmonary hypertensive crises.
- ECMO considerations: Iloprost can be particularly beneficial in ECMO patients who require prolonged treatment of pulmonary hypertension as it offers a longer duration of action than inhaled NO.

These agents are administered via inhalation, often through specialized delivery systems that can integrate with mechanical ventilation or into a high-flow nasal cannula. Continuous monitoring of pulmonary artery pressures and RV function is essential to evaluate the effectiveness of these agents. The selective pulmonary effects of these agents make them ideal for use in ECMO, as they can improve the pulmonary circulatory status without compromising systemic hemodynamics, thus supporting the overall goals of ECMO therapy and facilitation of the recovery process. Their use should be considered as part of a comprehensive approach to optimize cardiac and pulmonary conditions in critically ill patients on ECMO.

Vasopressors on ECMO

Vasopressors are used to maintain adequate vascular tone and perfusion pressure, especially in the context of vasodilatory shock or severe systemic inflammation. It is important to balance adequate vascular tone and VA ECMO flows, as increasing vascular tone can impair ECMO flows due to higher resistance. Additionally, there is the potential for a vasoplegic response to the ECMO circuit when initiating support. Although not very common, this can occur and may require vasopressor support until it resolves, usually within approximately 6 hours.

When managing patients on VA ECMO, it is also important to consider mean arterial pressure (MAP) goals. Maintaining an appropriate MAP is crucial, as excessively high MAP can increase afterload, which may reduce ECMO flows by increasing the resistance against which the ECMO circuit must pump. Therefore, careful titration of vasopressors is necessary to ensure optimal perfusion without compromising ECMO flow dynamics.

Norepinephrine.

- Mechanism: Strong α-adrenergic effects with moderate β-adrenergic effects, increasing systemic vascular resistance and arterial blood pressure.
- Indications: First-line agent for septic shock and widely used in cardiogenic shock to maintain coronary and cerebral perfusion pressures.
- ECMO considerations: Effective in maintaining systemic perfusion pressure without significant impact on cardiac output. The moderate β-adrenergic effect can be beneficial to overall cardiac function.

Vasopressin.

- Mechanism: Increases vascular smooth muscle tone via V1 receptor agonism, leading to an increase in systemic vascular resistance.
- Indications: Used in vasodilatory shock, particularly when response to other vasopressors is inadequate.
- ECMO considerations: Useful as an adjunct to norepinephrine for refractory hypotension; less likely to increase heart rate and cardiac output, reducing myocardial oxygen demand.

Phenylephrine.

- Mechanism: Pure α_1-adrenergic agonist that increases systemic vascular resistance and arterial pressure.
- Indications: Useful in situations where tachyarrhythmias need to be avoided or in combination with β-blockers.
- ECMO considerations: Can be used to increase perfusion pressure, especially useful in neurologic protection strategies.

The goal is to use the minimal effective doses of inotropes and vasopressors to achieve adequate organ perfusion while avoiding excessive myocardial workload and oxygen consumption. Each drug choice and its dosing must be tailored to the individual patient's underlying pathophysiology and response to ECMO support. It is also crucial to regularly reassess the need for continued pharmacologic support as the patient's condition evolves.

Antihypertensives on ECMO

Antihypertensives are essential in managing elevated blood pressure, which can compromise the effectiveness of ECMO support by limiting ECMO flows and increasing the risk of complications such as bleeding and stroke. The choice of antihypertensive agents and their administration must be carefully tailored to each patient's clinical scenario. Initial preference may be given to rapidly titratable agents for hypertension management, as they allow for precise control of blood pressure.

Agents like esmolol and labetalol are rarely useful on VA ECMO and are not commonly used in this setting. Typically, titratable antihypertensive agents are used until the patient can be weaned off ECMO. If a patient is on both antihypertensives and inotropes, efforts should focus on weaning the inotropes first to avoid the counterproductive effects of simultaneous administration.

Nicardipine.

- Mechanism: Calcium channel blocker that primarily acts on vascular smooth muscle to cause vasodilation, reducing systemic vascular resistance and arterial blood pressure.
- Indications: First-line agent for hypertensive emergencies and perioperative blood pressure management.
- ECMO considerations: Effective in controlling blood pressure without significant impact on heart rate or cardiac output. It can be titrated to achieve precise blood pressure targets.

Clevidipine.

- Mechanism: Dihydropyridine calcium channel blocker that causes arterial vasodilation, reducing systemic vascular resistance and blood pressure.
- Indications: Suitable for rapid blood pressure control in critically ill patients.
- ECMO considerations: Provides a rapid onset and short duration of action, allowing for precise blood pressure management.

Esmolol.

- Mechanism: Ultra-short-acting β-blocker that decreases heart rate, myocardial contractility, and cardiac output.
- Indications: Useful in controlling tachycardia and hypertension in the perioperative period or in patients with acute coronary syndromes.
- ECMO considerations: Beneficial in situations where heart rate control is crucial. The short half-life allows for rapid adjustment based on patient response.

Labetalol.

- Mechanism: Combined α- and β-adrenergic blocker that decreases systemic vascular resistance and myocardial contractility.

- Indications: Effective for both hypertensive emergencies and long-term blood pressure control.
- ECMO considerations: Useful in managing blood pressure with minimal reflex tachycardia; however, its β-blocking effects require caution in patients with compromised cardiac function.

Sodium nitroprusside.

- Mechanism: Direct vasodilator that acts on both arterial and venous smooth muscle to reduce systemic vascular resistance and venous return, lowering blood pressure.
- Indications: Used in hypertensive emergencies and acute heart failure.
- ECMO considerations: Effective in rapidly lowering blood pressure; however, its use requires close monitoring of cyanide and thiocyanate levels, particularly with prolonged use.

The overarching goal in the use of antihypertensives on ECMO is to maintain blood pressure within a therapeutic range that ensures optimal organ perfusion with a MAP of at least 65 mm Hg while minimizing the risk of adverse effects of an elevated MAP greater than 85 to 90 mm Hg. Regular monitoring and dose adjustments are necessary to respond to the dynamic changes in the patient's condition during ECMO therapy.

Left Ventricular Decompression on ECMO

LV decompression is critical in patients on VA ECMO. A distended left ventricle may be associated with increased afterload and or compromised contractility. The ramifications of LV distention include pulmonary edema, suboptimal coronary perfusion, and further LV injury reducing the likelihood of recovery. This problem is especially critical in patients who are unable to generate enough contractility on maximal inotropic support. In addition, if the LV is unable to generate enough force to open the aortic valve, the stagnant blood in the LV cavity and aortic root can lead to LV thrombus formation with possible embolization, aortic root thrombosis with catastrophic malperfusion of the coronary arteries.[37]

The following are detailed strategies for LV decompression.

Intraaortic Balloon Pump

- Mechanism: The IABP is inserted into the thoracic aorta, where it inflates during diastole to increase coronary blood flow and deflates before systole to decrease afterload, which reduces LV workload and promotes better cardiac output and LV decompression.[37]
- Indications: Typically used when there is moderate LV dysfunction, IABP can aid in offloading the LV, improving myocardial oxygen consumption, and enhancing coronary perfusion. However, studies have shown that IABP has limited usage on VA ECMO as it offers only minimal to no benefit in regard to LV unloading.

Impella

- Mechanism: The Impella device is a microaxial flow pump that is inserted across the aortic valve into the left ventricle. It actively pumps blood from the LV into the ascending aorta, directly unloading the LV, ensuring blood flow in the aortic root and providing end-organ perfusion (Fig. 116.10).[37]
- Indications: The Impella device is indicated in cases of severe LV dysfunction or when significant LV unloading is required. It is particularly useful in settings of cardiogenic shock or severe myocardial infarction with little to no pulsatility. Additionally, the Impella can be used to transition patients from VA ECMO or to evaluate isolated LV support in preparation for durable VAD implantation.

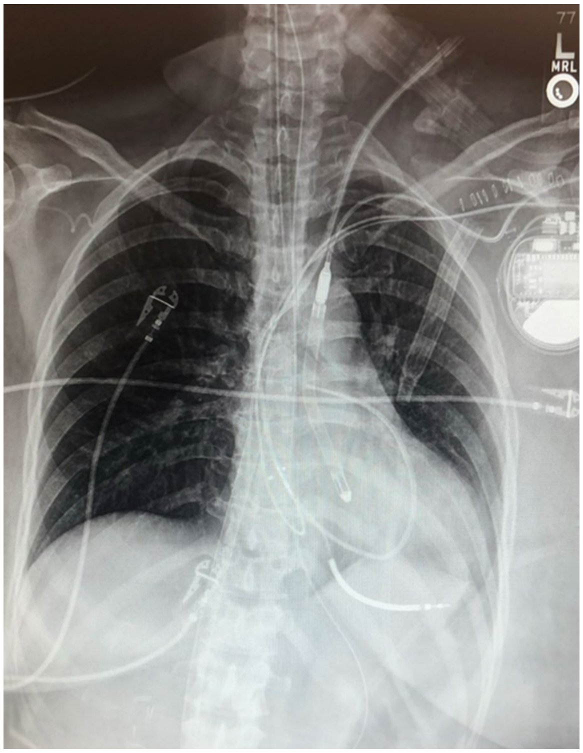

FIGURE 116.10 Venoarterial extracorporeal membrane oxygenation cannulation with Impella 5.5 in place for left ventricular decompression. (Courtesy UMMC: VA ECMO and Impella placement.)

Transseptal Left Atrial Decompression

- Mechanism: This procedure involves creating a shunt between the left atrium and the right atrium to reduce left atrial pressure and indirectly decompress the left ventricle by allowing blood to bypass the left ventricle. This shunt helps equalize atrial pressures and acts as a "pop-off" valve to avoid high LV end-diastolic pressure. By doing so, it can further facilitate diuresis and protect the lungs from the increased pressure. In some cases, an additional venous cannula can be inserted into the left atrium through this septostomy and connected to the primary venous drainage circuit.[37]
- Indications: Used in cases of severe pulmonary edema or when other methods are insufficient or contraindicated. This procedure is also often considered in pediatric patients or when there is a congenital heart anomaly complicating the clinical scenario.

Surgical Vent

- Mechanism: A surgical vent can be placed directly in the left atrium or ventricle during open surgery to actively drain blood, reducing intracardiac pressure and volume.[37]
- Indications: Considered in situations where rapid decompression is needed, or during cardiac surgery where direct access to the heart is already established.

Each of these management strategies requires careful consideration of the individual patient's hemodynamic profile and underlying cardiac pathology. Implementing these strategies effectively can significantly influence the prognosis and outcome of patients on ECMO.

Harlequin Syndrome and VA ECMO

Harlequin Syndrome Overview

Harlequin syndrome, also known as North-South syndrome, occurs predominantly in patients on peripheral VA ECMO who have severe pulmonary dysfunction. This condition is characterized by differential oxygenation that may lead to cerebral hypoxia, in which the upper body, including the brain and upper extremities, receive deoxygenated blood from that patient's native cardiac output that ejects hypoxic blood returning from poorly functioning lungs, while the lower body receives oxygenated blood from the ECMO circuit.[34,38,39]

Mechanism

This syndrome arises because peripheral VA ECMO typically returns oxygen-rich blood preferentially to the lower body and visceral organs before perfusing the upper body and brain. Meanwhile, the native heart continues to pump deoxygenated blood from the lungs into the aorta, which preferentially perfuses the upper body with poorly oxygenated blood.[34,38,39] This results in a visible discrepancy in oxygenation between the upper and lower halves of the body. There are additional concerns that coronary oxygenation can also be compromised, as coronary perfusion is primarily supplied by the native heart.

This issue becomes particularly concerning when heart function improves or if myocardial depression was initially due to hypoxia or poor lung function in a patient placed on VA ECMO emergently or in the setting of ECPR (Fig. 116.11).

Management of Harlequin Syndrome

Adjust cannulation sites: One approach to managing Harlequin syndrome is to change the cannulation strategy to central ECMO or to a different peripheral site that might offer better mixing of blood.

In managing Harlequin syndrome in patients on peripheral VA ECMO, medical management primarily focuses on optimizing both ECMO flow and native heart function to ensure more uniform blood oxygenation.[20]

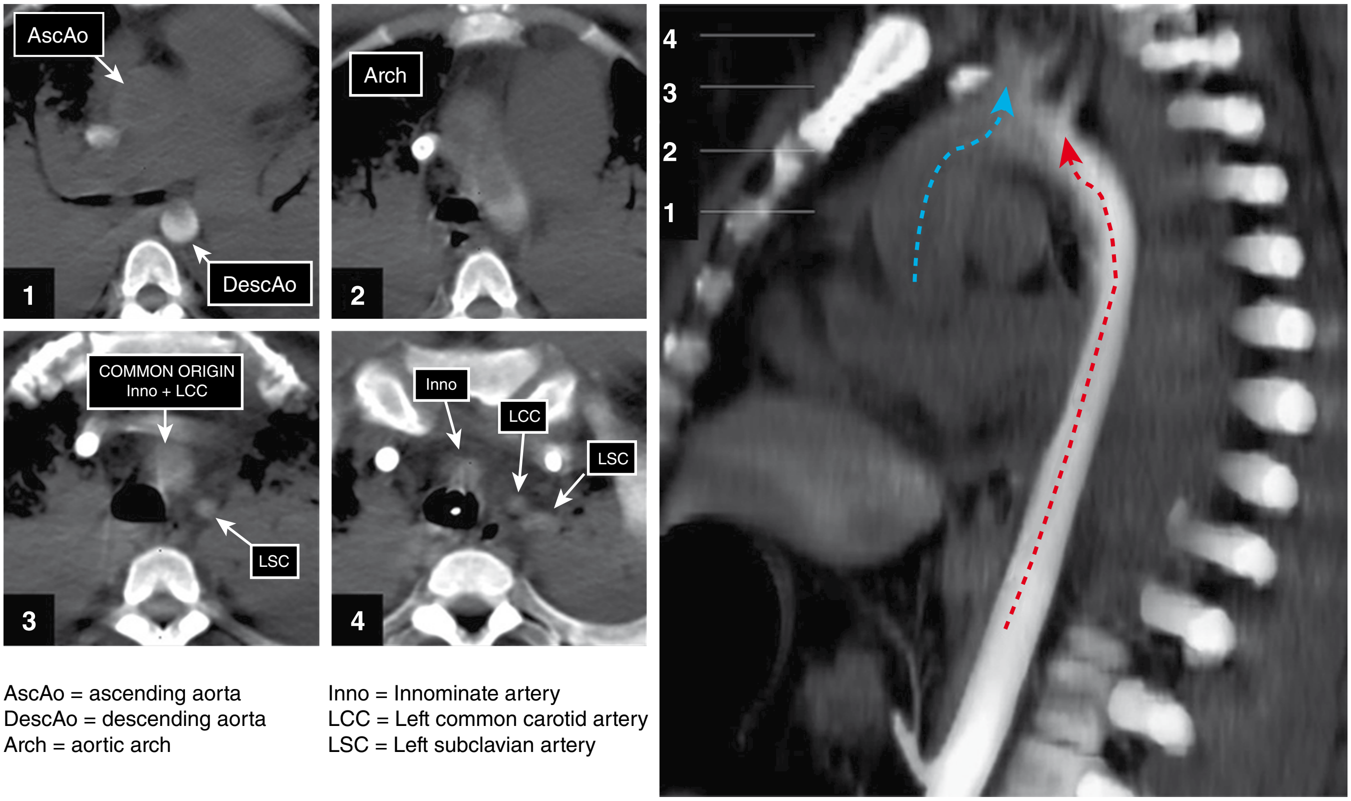
Increase and optimize ECMO flow: Adjusting the flow rate of the ECMO can help ensure that more oxygenated blood is mixed and circulated throughout the body. This can be particularly effective in overcoming the gradient differences between the deoxygenated blood from the heart and the oxygenated blood from the ECMO circuit.

Monitoring and adjustments: Continuous monitoring of ABGs from the upper body through the right radial artery provides an estimate of the oxygenation quality to the aortic arch and upper body. These arterial gas measurements allow for a dynamic assessment and a means to measure the effectiveness of the flow adjustments.

Modulating Cardiac Output

Inotrope reduction: If cardiac output is too high as the heart begins to recover, inotrope reduction should be considered to reduce overall cardiac output.

Volume removal: Aggressive volume removal can be used to reduce overall cardiac output. In this setting, the goal is to fully



AscAo = ascending aorta
DescAo = descending aorta
Arch = aortic arch

Inno = Innominate artery
LCC = Left common carotid artery
LSC = Left subclavian artery

FIGURE 116.11 Radiographic findings of Harlequin syndrome. Axial *(left)* and oblique *(right)* maximum intensity projection images from chest CT angiography demonstrate antegrade flow in the ascending aorta and right-sided great vessels via native cardiac ejection *(blue arrow)* and retrograde flow in the descending aorta via the femoral extracorporeal membrane oxygenation cannula with preferential flow to the left subclavian artery *(red arrow)*. (From Pasrija C, Bedeir K, Jeudy J, Kon ZN. Harlequin syndrome during venoarterial extracorporeal membrane oxygenation. *Radiol Cardiothorac Imaging*. 2019;1[2]:e190031.)

decompress the RV and shunt the remaining blood volume into the ECMO circuit.

Heart rate control: Medications such as β-blockers can be used to manage tachycardia and reduce cardiac output, allowing for less flow through the impaired pulmonary system reducing the impact of the native heart ejection of deoxygenated blood. However, this should be a last resort and if medications such as β-blockers are indicated, then the patient should be considered for decannulation or reconfiguration to VV ECMO.

Enhancing Oxygenation

Supplemental oxygen: Increasing the FiO_2 to the patient can sometimes help improve the oxygenation of the blood ejected by the native heart.

Adjustments in ventilatory support: Done to modify ventilator settings to optimize gas exchange in the lungs, which can help increase the oxygen content of the blood leaving the heart.

Bronchoscopy: It is important to evaluate patient airways to rule out any forms of reversable obstruction such as a mucus plug.

Cannulation Reconfiguration

Transition from VA to VV ECMO: Patients who have recovered from a cardiac perspective, but still have significant respiratory compromise, should be considered from possible transition from VA ECMO-focused to VV ECMO-focused respiratory support. This evaluation should be performed before consideration for V-AV ECMO.

Transition from VA ECMO to V-AV ECMO: For patients with combined cardiac and respiratory failure, V-AV ECMO combines elements of both VV and VA ECMO, making it uniquely suited to address the challenges of Harlequin syndrome by balancing the oxygenation across the body more effectively. In the V-AV ECMO setup, blood is typically drawn from a central vein like the internal jugular or femoral vein (venous drainage), oxygenated externally, and then part of the oxygenated blood is returned to an artery (arterial return) to support the systemic circulation, while another portion is returned to a vein, enhancing the pulmonary circulation.[39]

The implementation of V-AV ECMO requires careful planning and precise cannulation to ensure effective blood flow management. It is crucial to monitor the oxygen saturation levels in different parts of the body to adjust the flow rates and oxygen delivery according to the patient's needs. Continuous monitoring and adjustments are necessary to maintain the balance between the venous and arterial components, adapting to changes in the patient's condition and requirements (Fig. 116.12).

Additional considerations include the use of flow probes to monitor return flow for both venous and arterial components and to make necessary adjustments. There is a higher risk of clot formation and hemolysis with V-AV ECMO due to the split return flow, which requires vigilant monitoring and management to mitigate these risks.

Each of these strategies requires a tailored approach based on the specific clinical situation of the patient. Continuous monitoring, including echocardiography and ABG analysis, is vital to ensure that interventions are effectively addressing the physiologic challenges presented by Harlequin syndrome. These targeted approaches help mitigate the risks associated with Harlequin syndrome and ensure optimal outcomes for patients undergoing ECMO therapy.

(From Shah A, Dave S, Goerlich CE, Kaczorowski DJ. Hybrid and parallel extracorporeal membrane oxygenation circuits. *JTCVS Tech.* 2021;8:77-85.)

Sedation Goals

The sedation goals on VA ECMO are crucial for ensuring patient comfort, safety, and optimal management of the ECMO circuit.[15,40] The following are the main objectives when considering sedation for patients on VA ECMO:

Patient comfort: Minimize discomfort and anxiety caused by the ECMO cannulas and other invasive lines. Reduce awareness during a potentially distressing critical care environment.

Safety: Prevent dislodgement of lines and cannulas by minimizing patient movement and agitation. Ensure that the patient does not interfere with the ECMO circuit or other critical devices.

Facilitate ventilation and oxygenation: For patients who are mechanically ventilated, ventilator synchrony for those who are partially awake and breathing spontaneously is important to consider when optimizing sedation.

Hemodynamic stability: Use sedatives that have minimal impact on hemodynamic stability and ECMO flow stability as agitation and the vasovagal response can interfere with ECMO flows if significant enough.

Reduce metabolic demand: Lower the overall metabolic demand of the body, which is crucial in situations of compromised severely compromised cardiac function.

Overall, the sedation plan for VA ECMO patients needs to be individualized, considering their specific clinical situation, response to treatment, and overall goals of care.

Rehabilitation Goals

All ECMO patients require an evaluation from the rehabilitation services and receive physical therapy with active mobilization. Ambulation of patients on VA ECMO is feasible and is a growing area of interest in critical care, as it can potentially improve outcomes by enhancing physical conditioning, psychological well-being, and recovery rates.[15,40,41] The process of mobilizing patients while on ECMO, particularly peripheral VA ECMO, is complex and requires careful coordination (Fig. 116.13). The following section includes some key considerations and notable challenges involved in ambulating patients on VA ECMO.

Key Considerations

Patient stability: The patient must be hemodynamically stable with adequate organ function and physical conditioning.

Team coordination: A multidisciplinary team approach is required, including physicians, nurses, physical therapists, and respiratory therapists.

Equipment management: Special attention is needed to manage the ECMO circuit and other associated devices to prevent dislodgment or complications during movement.

Challenges and Precautions

Risk of cannula displacement: Movement can increase the risk of dislodging the ECMO cannulas, which is potentially life-threatening.

Bleeding risk: Patients on ECMO are typically on anticoagulation therapy, increasing the risk of bleeding with physical activity, especially from around the cannulation sites.

Weaning and Decannulation

Weaning and decannulation from VA ECMO are critical phases in the management of patients who have been supported on ECMO for cardiac dysfunction. The process involves carefully assessing the patient's recovery and readiness to resume independent function of their heart function. The following is a detailed overview of the process.

Weaning From ECMO

Assessment of recovery: The first step involves evaluating whether the patient's heart function and hemodynamics will be able to function independently. This typically involves a series of tests including echocardiograms, blood gas analyses, and hemodynamic monitoring to assess cardiac output and respiratory function.

Trial weaning or RAMP study: A RAMP (gradual flow reduction) study is a structured assessment of cardiac function performed while reducing VA ECMO flow to evaluate myocardial recovery and readiness for decannulation. During a RAMP study, the VA ECMO flow is gradually reduced while closely monitoring the patient's response. This process can be done in the ICU using a transthoracic echocardiogram or transesophageal echocardiogram to specifically capture the heart function and loading volumes of the patient at specific flow speeds.[25,42,43] Monitoring hemodynamics is critical during this process. Consider holding antihypertensive medications or increasing inotropes as needed to assess how the patient can transition off ECMO. The ability to maintain adequate oxygenation and stable hemodynamics with reduced ECMO support is a key indicator of readiness for decannulation.

Decannulation From ECMO

Timing and preparation: Decannulation is considered when a patient has demonstrated stable heart function on minimal to no ECMO support. Preparing for decannulation involves ensuring that anticoagulation levels are appropriate to minimize the risk of bleeding, and that all necessary surgical or medical staff are available.

The decannulation procedure involves surgically removing the ECMO cannulas, usually under sterile conditions in the ICU or

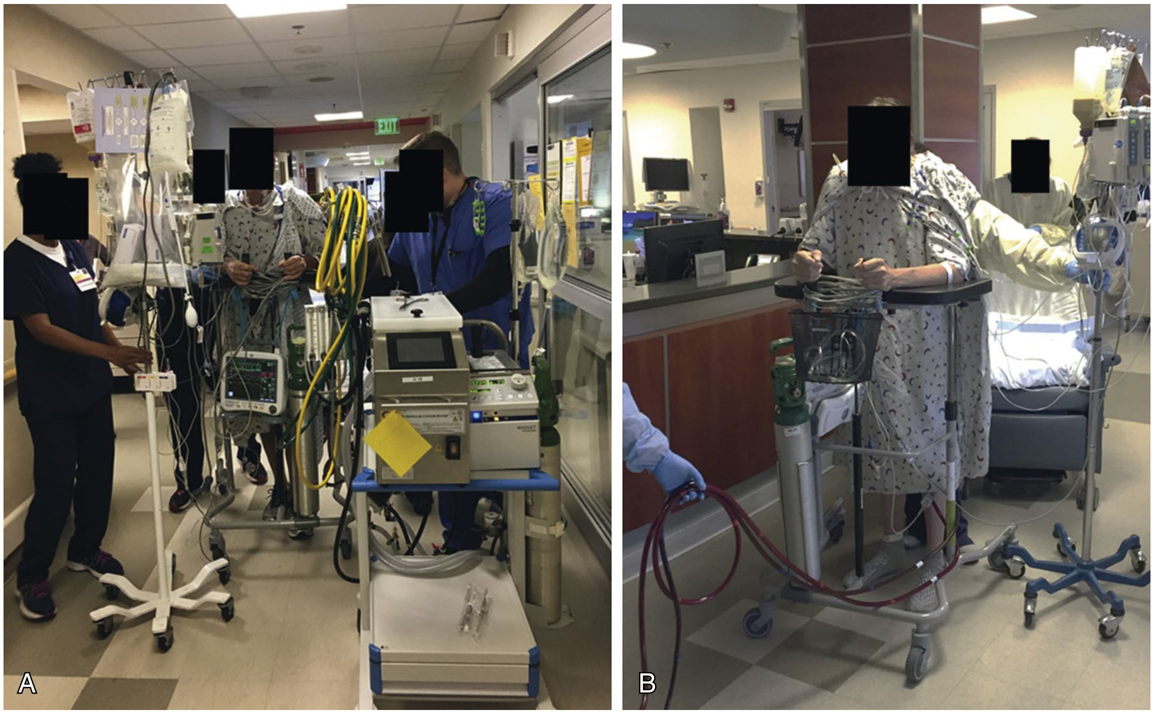


FIGURE 116.13 (A) A patient ambulating 42 days after venoarterial extracorporeal membrane oxygenation (VA ECMO) cannulation with the nurse, physical therapist, advanced care provider, and ECMO specialist. The patient monitor is readily visible for the nurse, and the ECMO specialist is monitoring the tubing length. (B) A patient ambulating 13 days after VA ECMO cannulation. (From Pasrija C, Mackowick KM, Raithel M, Tran D, Boulos FM, Deatrick KB, et al. Ambulation with femoral arterial cannulation can be safely performed on venoarterial extracorporeal membrane oxygenation. *Ann Thorac Surg.* 2019;107[5]:1389-1394.)

operating room. The sites of cannulation are then closed either via surgical revision or using vascular closure devices, depending on the size of the cannulas, location of the cannulation, and the condition of the vessels.[44–46]

After the cannulas are removed, patients require close monitoring for any signs of bleeding, infection, or recurrence of cardiac dysfunction.

Challenges and Considerations

Decisions around weaning and decannulation should consider individual patient factors such as underlying diseases, the duration on ECMO, and overall recovery progress. It is important that goals of care are discussed with the patient and their families, and that it is made clear if the patient is a candidate for recannulation and initiation of ECMO therapy if they were to decompensate again.

Weaning and decannulation from ECMO are complex processes that require a multidisciplinary approach, involving intensive care physicians, cardiothoracic surgeons, nurses, respiratory therapists, and other specialists. Careful planning, adherence to evidence-based protocols, and patient-centered care are essential to optimize outcomes and minimize complications.

Extracorporeal Cardiopulmonary Resuscitation

ECPR is a resuscitation strategy for patients in cardiac arrest that incorporates rapid ECMO cannulation to provide mechanical support to help achieve a return of spontaneous circulation (ROSC).[21] It is used when a patient in cardiac arrest fails to respond to conventional CPR and provides both hemodynamic and respiratory support during the resuscitative efforts. The overall 30-day survival rate for adult patients undergoing ECPR is 30%, whereas the pediatric survival rate stands at 41%.[1]

Extracorporeal Cardiopulmonary Resuscitation Process

Assessment and initiation: The decision to initiate ECPR is usually made when conventional CPR is not effective within the first 15 minutes of cardiac arrest. Quick assessment of the patient's condition, likelihood of survival, associated significant comorbidities, and the feasibility of ECPR is crucial.[47] Although there are no absolute inclusion or exclusion criteria, several proposed ECPR considerations have published to help quickly identify potential candidates. Finally, early activation of the ECMO team facilitates these time-sensitive ECPR assessments, considerations, and cannulations.[47]

Cannulation: The cannulation procedure for ECPR typically involves ultrasound-guided rapid vascular access and cannula insertion for emergent peripheral VA ECMO initiation. This is usually performed via the femoral vein and contralateral femoral artery. This must be done swiftly and accurately to rapidly restore circulation and oxygenation while minimizing the risk of technical errors and complications.[22] During an ECPR resuscitation, the priority should be successful cannulation and initiation of ECMO, whereas a distal perfusion cannula can be placed later at bedside, in the cath lab, or in the operating room after the patient has been stabilized on ECMO support.

Post-ECPR care: Management of an ECPR patient after achieving ROSC involves a careful determination of the underlying cause of cardiac arrest and consideration for procedural interventions such as a PCI. Pulsatility must be maintained while the heart cannot be allowed to distend. Management considerations for these goals include optimization of inotropic support, insertion of an IABP, creation of a septostomy, or placement of an Impella or other left-heart unloading technique.[22,37] Patients require continuous hemodynamic, neurologic, and respiratory monitoring with adjustment of ECMO settings and vasoactive infusions to help maintain adequate end-organ perfusion and oxygenation. Neurologic assessment should be prioritized and neurocritical care should be consulted once ECMO support is initiated to optimize postarrest neurologic recovery.[22,24]

Indications and Contraindications[21]

Indications.

- Refractory cardiac arrest: When conventional CPR does not result in ROSC.
- Witnessed arrest: Especially in the presence of healthcare providers with immediate CPR and availability of rapid ECMO deployment.
- Potentially reversible cause: When the underlying cause of the cardiac arrest can potentially be treated (e.g., massive pulmonary embolism, myocardial infarction, drug toxicity).

Contraindications.

- Prolonged cardiac arrest without CPR: If the cardiac arrest is unwitnessed and CPR is delayed, leading to a significant period without perfusion.
- Severe comorbid conditions: Terminal illnesses or severe multiorgan failure that does not warrant aggressive life-support measures.
- Unrecoverable neurologic status: Patients with significant baseline neurologic impairments or those who are expected to have poor neurologic outcomes even if resuscitation is successful.
- Severe trauma: Especially where hemorrhage control is not feasible, making ECMO counterproductive or dangerous.

The decision to use ECPR involves critical consideration of the patient's overall prognosis, the rapid availability of ECMO technology, and a multidisciplinary team capable of performing this complex procedure.

SPECIAL CIRCUMSTANCES AND ECMO

Trauma: ECMO is increasingly considered in trauma patients with severe cardiopulmonary failure when conventional therapies fail. It can be particularly beneficial in cases of severe chest trauma with pulmonary contusions and severe respiratory failure. VV ECMO has also been successfully used to support patients after a traumatic pneumonectomy, whereas VA ECMO may be considered in cases of cardiogenic shock secondary to a structural cardiac injury. However, the risk of bleeding due to anticoagulation required during ECMO is a significant concern, especially in patients with active hemorrhage or traumatic brain injury (TBI).[9]

Concomitant neuropathology: Using ECMO in patients with neurologic injuries (such as bleed, cerebrovascular accidents [CVAs], TBI, or recent neurosurgery) is complex due to the need for anticoagulation, which poses a risk of exacerbating or causing new intracranial hemorrhages.[48] The decision to initiate ECMO involves careful risk-benefit analysis, often considering the extent of brain injury and the potential for neurologic recovery. Although there has been an increase in the successful utilization of ECMO in this patient population, concomitant neuropathology should not be considered an ßabsolute contradiction for ECMO initiation.

Septic shock: ECMO may be used in septic patients who develop severe ARDS or refractory septic shock, particularly when there is suspected sepsis-driven cardiac depression. It supports oxygenation and circulation while potentially allowing the heart and lungs to recover from sepsis-induced damage. However, ECMO does not address the underlying infection and inflammation, and meticulous management of the source of infection and supportive care are crucial. Due to the vasodilation associated with profound sepsis, managing ECMO flows and providing adequate support can be uniquely challenging in this hypermetabolic state.[49]

To determine whether ECMO will be beneficial in septic shock, it is important to assess cardiac output and heart function. This can be done using a Swan-Ganz catheter to measure cardiac output and echocardiography to evaluate heart function. If cardiac output is high and echocardiography shows good heart function, ECMO is unlikely to help in septic shock as the issue is not cardiac depression but rather vasodilation and hypermetabolism.[49]

Hypothermia: ECMO circuits incorporate precise thermoregulation capabilities through built-in heat exchangers, allowing for targeted control of patient body temperature. This feature is particularly crucial in the management of severe accidental hypothermia, especially in instances complicated by cardiac arrest. By using ECMO, clinicians can meticulously manage the rewarming process, ensuring it is gradual and controlled to prevent the complications associated with rapid temperature changes.[50] The capability to precisely adjust the ECMO temperature settings and control a patients' body temperature not only supports essential physiologic functions during this critical time but also significantly enhances patient outcomes in conditions that might otherwise prove fatal.[50]

Drug overdose: In cases of severe drug overdose resulting in cardiac or respiratory failure, ECMO can be a lifesaving modality. It provides supportive care allowing time to metabolize and clear the toxic substances. Specific scenarios include overdoses of drugs like β-blockers, calcium channel blockers, or opioid overdose resulting in aspiration, with failed attempts of medical management.[51]

Transplant: ECMO is used as a bridge to transplant in patients with end-stage heart or lung disease. It stabilizes patients until a suitable organ becomes available and can also support post-transplant patients through acute phases of graft dysfunction or rejection.[32,52]

Each of these scenarios requires careful consideration of the patient's specific conditions, potential benefits, and risks associated with ECMO. Decision-making typically involves a multidisciplinary team of specialists, including surgeons, critical care physicians, cardiologists, and others to address the broad implications of ECMO therapy. Its use in such special circumstances often necessitates tailored approaches, balancing the benefits of ECMO support against potential complications, especially bleeding and infection risks.

ECMO COMPLICATIONS

Complications associated with ECMO can vary widely depending on the patient's condition, the duration of ECMO support, and the specific ECMO modality and configuration that is used (VA vs. VV vs. V-AV and peripheral vs. central).

Low flows and ECMO chatter/chugging: Low flow and chatter (or chugging) can occur due to hypovolemia, cannula mispositioning, or thrombosis within the circuit. This results in inadequate flow rates that can cause the ECMO pump to function intermittently or "chug." Regular monitoring and adjustments to fluid status, cannula placement, and anticoagulation can help manage this issue. It is also important to evaluate the patient for any potential signs of abdominal compartment syndrome that can result in compression of the IVC and impaired ECMO flow.[53–55]

Bleeding: Bleeding is a common complication due to the systemic anticoagulation necessary for ECMO operation. It can occur at surgical sites, cannulation sites, or internally. Managing anticoagulation meticulously and monitoring for signs of bleeding are crucial.

Infection: Infections can arise from cannula sites or within the ECMO circuit itself. Strict adherence to sterile procedures during cannulation and routine care, frequent site inspections, and prophylactic antibiotic strategies are important to minimize this risk.[45]

Hemolysis: Hemolysis can occur due to the mechanical forces within the ECMO circuit. Monitoring laboratory markers such as lactate dehydrogenase, plasma-free hemoglobin, and transmembrane pressures aid in early detection.[56] It is important to closely examine all circuit components for thrombus formation as this can contribute to the hemolysis. Hemolysis can often be mitigated with adjustments to the ECMO flows, component changes such as an oxygenator exchange if indicated, and circuit changes if the patient still requires ECMO support, but in severe cases ECMO decannulation may be warranted.

Extremity ischemia: Ischemia of the extremities can occur due to impaired blood flow related to cannulation, particularly with femoral artery cannula insertions. Routine placement of an antegrade distal perfusion cannula in the superficial femoral artery on the arterial cannulation side can mitigate this risk.[57] If there are concerns for malperfusion with a distal perfusion line in place, a bedside angiogram down the distal perfusion catheter can be used to confirm positioning and flow (Fig. 116.14). Additionally, monitoring techniques such as near-infrared spectroscopy or Doppler/pulse monitoring can be employed to assess perfusion. It is important to note that any Doppler signals of the specific extremity may be continuous. The distal perfusion cannula can be momentarily shut off to evaluate any changes in the signal if there is a concern regarding flow.

Neurologic Complications

- Lower extremity paralysis is a rare complication but may occur due to spinal cord ischemia.[58] One suggested theory is abnormal turbulent flow as the retrograde ECMO flow of peripheral VA ECMO mixes with the native cardiac output. It has been proposed that adjustments may be made to the ECMO flow rates to alter the location of this turbulent "mixing zone." It may be necessary to consider prompt decannulation from VA ECMO in this scenario. Further studies are needed to fully understand the etiology of this rare complication.[58]
- CVAs can occur due to thromboembolic events or hemorrhages, exacerbated by the altered coagulation state on ECMO.[59]

DVT: This is a risk due to reduced mobility and vascular endothelial trauma from cannulas. Systemic anticoagulation while on ECMO helps mitigate that risk, whereas post-decannulation monitoring allows for early detection.[19]

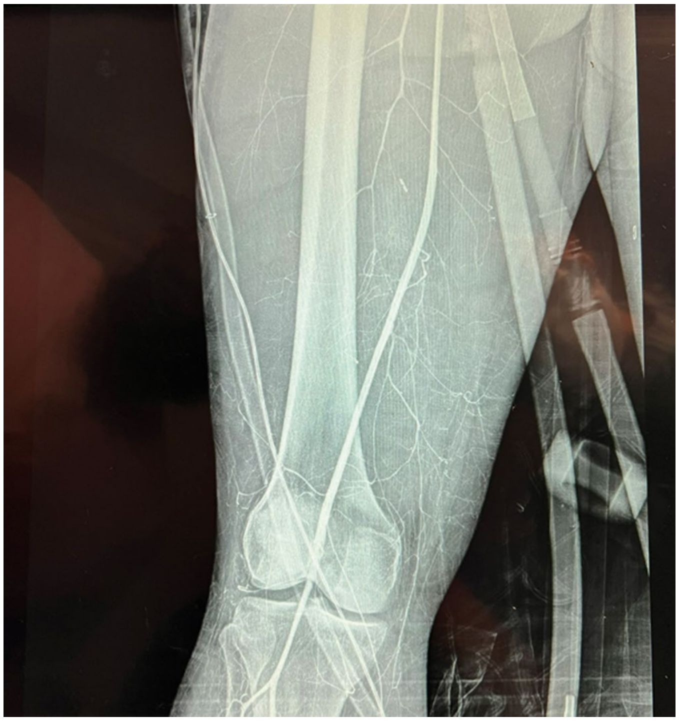

FIGURE 116.14 Bedside angiogram performed by directly injecting water-soluble contrast through the distal perfusion sheath. (Courtesy UMMC: Distal perfusion angiogram done in the intensive care unit.)

Wounds and deconditioning: Long-term ECMO support can lead to pressure ulcers, muscle wasting, and general physical deconditioning. Regular repositioning, nutritional support, and, where possible, physical therapy are essential for managing these issues.

Each of these complications requires proactive management and interdisciplinary teamwork to mitigate risks and improve outcomes for patients on ECMO. Addressing these challenges promptly and effectively is key to maximizing the therapeutic benefits of ECMO while minimizing adverse effects.

MULTIDISCIPLINARY APPROACH

Management of ECMO patients requires a multidisciplinary approach involving specialized consultants in addition to the surgical team for comprehensive care. Physical and occupational therapists play a critical role in maintaining and enhancing patient mobility to prevent muscle atrophy. Nutritionists ensure that patients receive tailored nutritional support to meet the metabolic demands, reduce the risk of malnutrition, and support recovery. Infectious disease specialists are crucial for managing infections, a common risk due to the invasiveness of ECMO and associated immunocompromised states.

Specialists in heart failure and pulmonary transplant assess and manage patients when ECMO is used as a bridge to transplant, providing vital support in complex cardiopulmonary cases. Finally, the palliative care service is integral in addressing quality-of-life concerns, ensuring that care aligns with the patient's and family's wishes, particularly in end-of-life scenarios. Together, these consultants form a vital network that supports the diverse needs of ECMO patients, enhancing outcomes and facilitating comprehensive care.

CHALLENGES: FUTILITY

Clinical assessment of futility: Determining futility involves evaluating the likelihood of recovery or significant improvement with continued ECMO support. This requires a thorough understanding of the patient's underlying condition, the trajectory of their illness, and the potential for reversibility of their acute condition. Clinicians often rely on a combination of clinical judgment, ethical frameworks, and evidence-based guidelines to make these determinations.

Ethical and emotional considerations: Discussions around futility can be emotionally challenging for both the healthcare team and the patient's family. It involves balancing hope for recovery with the realistic outcomes of continued treatment. Ethical dilemmas arise when considering the patient's quality of life posttreatment, the potential for suffering, and the judicious use of medical resources.

Communication and decision-making: Effective communication is crucial when discussing the possibility of futility. Engaging in open and honest dialogue with family members and among the care team is essential. These discussions should ideally involve multidisciplinary team members, including ethics consultants when available, to provide a well-rounded perspective on the patient's care options.

End-of-life care planning: When ECMO is deemed futile, the focus shifts toward palliative care and end-of-life decision-making. Ensuring comfort, managing symptoms, and supporting the family emotionally and psychologically become the primary goals. Discussions about withdrawing ECMO support are sensitive and should be handled with utmost care, respecting the dignity and wishes of the patient and their family.

The challenge of futility on ECMO underscores the need for ongoing ethical education and support for healthcare providers, enabling them to navigate these difficult decisions effectively and compassionately.

SUMMARY

ECMO is a significant advancement and powerful resource in cardiopulmonary critical care, offering life-sustaining mechanical support for patients with severe cardiac and respiratory failure when conventional treatments have failed. ECMO can be life saving. This technology provides patients with a bridge to recovery, a bridge to transplantation, or time that supports intricate decision-making. The application of ECMO spans various scenarios showcasing its versatility in supporting complex medical conditions not amenable to conventional management.

However, the use of ECMO is not without challenges. It requires meticulous management of potential complications such as bleeding, infection, neurologic injury, and malnutrition. The decision to initiate or discontinue ECMO involves ethical considerations, particularly in determining futility, which requires careful communication and decision-making with patient families and within the care team. As ECMO technology evolves and becomes more integrated into clinical practice, the focus remains on enhancing patient outcomes, refining techniques, and expanding the knowledge and skills of the multidisciplinary teams that manage these complex interventions. This ongoing development underscores ECMO's critical role in modern medicine, providing not just a chance for survival but also a testament to the advancements in patient care and critical care technology.

- **Pediatric Critical Care: Extracorporeal Life Support**

Pediatric surgery remains the last bastion of true general surgical specialty. Pediatric surgical conditions span fetal to neonatal, adolescent, and young adults. Pediatric surgeons must assess and manage a wide spectrum of surgical conditions with vastly different pathophysiology. In recent decades, there has been an increasing trend to develop subspecialties of pediatric surgery, such as colorectal, pediatric surgical oncology, and chest wall deformity programs. They cover a wide spectrum of organ systems ranging from head and neck to thoracic and the gastrointestinal (GI) tract. This chapter will provide an overview of common and unique pediatric surgical conditions and their pathophysiology and treatment strategies.

NEONATAL PHYSIOLOGY

The newborn physiology is unique in terms of their smaller physiologic capacity and cellular and functional immaturity of organ systems. Newborns are at risk for cold ambient temperatures, and an ideal thermal environment must be maintained to reduce oxygen consumption and metabolic demands. The major risk factors for hypothermia in infants include a relatively large body surface area compared with body weight, limited subcutaneous fat, and increased insensible fluid losses. Infants also respond to cooler ambient temperatures by nonshivering thermogenesis, whereby increases in metabolism and oxygen consumption occur.

Thermoregulated isolettes are commonly used to keep an ideal ambient temperature (~23°C) to maintain the neonate's core body temperature between 36°C and 37.5°C.

Cardiopulmonary

During fetal circulation, arterial blood from the placenta bypasses the fetal lungs through the patent foramen ovale and ductus arteriosus. After birth, the foramen ovale closes with the newborn's first breath, then a precipitous drop in pulmonary vascular resistance occurs, increasing pulmonary blood flow. Decreased blood flow, along with a higher oxygen content, promotes spontaneous closure of the ductus arteriosus. Pulmonary vascular resistance is increased by hypoxemia and acidosis, resulting in persistent pulmonary hypertension (PPHN) and right-to-left shunt. Nonsteroidal anti-inflammatory agents (i.e., indomethacin) can promote the closure of a patent ductus arteriosus in premature infants. If persistently open, patent ductus arteriosus closure is achieved by catheter-based coil procedure and, on occasion, a traditional open surgical ductal ligation. The infant heart has a limited capacity to increase the stroke volume; cardiac output is largely heart rate dependent. Heart rate change and capillary refill are sensitive indicators of intravascular volume status and tissue perfusion, respectively.

At birth, the lungs are considered functionally immature, and they continue to develop new terminal bronchioles and alveoli until 6 to 8 years of age. The neonatal lung has fewer type II pneumocytes, which produce surfactant, a lipoprotein mixture of phospholipid, protein, and neutral fats. Surfactant regulates alveolar surface tension, thereby increasing functional residual capacity. Lecithin, the most predominant phospholipid, can be measured in amniotic fluid, and the lecithin to sphingomyelin ratio is used to determine fetal lung maturity. Premature infants are at greater risk for alveolar collapse, hyaline membrane formation, and barotrauma from mechanical ventilatory support. Also, the newborn airway is quite small, with an average tracheal diameter of 2.5 to 4 mm, and can easily be plugged with airway secretions. The respiratory rate for a healthy newborn ranges from 40 to 60 breaths/min, with a tidal volume of 6 to 10 mL/kg. Nasal flaring, grunting, intercostal and substernal retractions, and cyanosis are symptoms and signs of respiratory distress. Infants are obligate nasal and diaphragmatic breathers; therefore, any condition that obstructs the nasal passages (e.g., nasogastric tube) or interferes with diaphragmatic function may severely compromise respiratory status. Exogenous surfactant therapy has resulted in improved survival of premature infants and decreased incidence of bronchopulmonary dysplasia, a condition characterized by oxygen dependence, radiologic abnormality, and chronic respiratory symptoms beyond the first 28 days of life. Nitric oxide gas, a potent inducer of vascular smooth muscle relaxation, is also effective against PPHN.

Immunology

Infants have lower levels of immunoglobulins (IgA, G, and M) and of the C3b complement at birth, so they are at higher risk for systemic infection. A sepsis workup for neonates includes surveillance cultures of various bodily fluids—such as cerebrospinal fluid—as well as routine blood laboratory tests. Infants are also at risk for potential septic sources arising from invasive vascular catheters and interventions such as prolonged endotracheal intubation and bladder catheterization, which can contribute to hospital-acquired conditions. An empirical antibiotic regimen is often started based on subtle clinical suspicions (e.g., decreased tolerance of enteral feeding, temperature instability, reduced capillary refill, tachypnea, irritability). Antibiotic therapy is targeted at common bacterial pathogens, such as Group B β-hemolytic streptococcus, methicillin-resistant *Staphylococcus aureus,* and *Escherichia coli.*

FLUIDS, ELECTROLYTES, AND NUTRITION

Fluid and Electrolytes

Fluid and electrolyte balance must be carefully assessed in pediatric surgical patients, especially in neonates and small toddlers with a narrower margin for error. Due to higher insensible water losses through a thin, immature skin barrier, fluid requirements for premature infants can be substantial. Insensible water losses are directly related to gestational age, which ranges from 45 to 60 mL/kg/day for premature infants weighing less than 1500 g to 30–35 mL/kg/day for term infants. Radiant heat warmers, phototherapy for hyperbilirubinemia, and respiratory distress can result in additional fluid losses. During the first 3 to 5 days of life, physiologic water loss can be up to 10% of the body weight. Fluid requirements are calculated according to body weight. During the first few days, the fluid recommendations are on the conservative side; however, infants require 100 to 130 mL/kg/day for maintenance fluids by the fourth day of life. Surgical conditions such as gastroschisis and necrotizing enterocolitis (NEC) demand significantly higher volume. Urine output and osmolarity are good indicators of adequate tissue perfusion. The ideal minimum urine output in a newborn is 1 to 2 mL/kg/day. Infants can respond to prerenal azotemia by concentrating urine only up to approximately 700 mOsm/kg. The daily requirements for sodium and potassium are 2 to 4 and 1 to 2 mEq/kg, respectively. These requirements are usually met with 5% dextrose in 0.45% normal saline (NS) with 20 mEq/L of potassium at the calculated maintenance rate. Fluid losses from gastric drainage, ostomy output, or diarrhea should also be carefully assessed and replaced with an appropriate solution. Gastric losses should be replaced in equal volumes with 0.45% NS with 20 mEq/L of potassium. Diarrheal, pancreatic, and biliary losses are replaced with isotonic lactated Ringer solution. Hypovolemia due to acute hemorrhage should be corrected with prompt transfusion of blood products at a bolus of 10 to 20 mL/kg of packed red blood cells, plasma, or 5% albumin.

Nutrition

Energy requirements vary substantially from infancy to childhood. Appropriate weight gain is the most reliable clinical indicator of adequate caloric consumption. Total daily caloric requirements and the weight curve plateau with age. Nearly 50% of the energy in term infants younger than 2 weeks and 60% of energy in premature infants <1200 g are consumed for growth. A general guideline for the enteral calorie requirement of infants is 120 calories/kg/day to achieve an ideal weight gain of ~1% of body weight per day. The standard infant formulas, as well as breast milk, contain 20 calories/ounce. Formulas with higher calorie density are available for infants who are unable to consume sufficient volumes to meet their calorie requirements or those with strict fluid restrictions. Breast milk is the ideal form of enteral nutrition. However, hypoallergenic, lactose-free to amino acid–based formulas are available to meet the specific needs of infants with particular GI tract conditions. In general, continuous enteral feedings are used for infants with a stressed gut and then transitioned to gastric bolus feedings. The enteral feeding tolerance is carefully monitored by assessing for abdominal girth, gastric residuals, and stool output.

Carbohydrates are stored mainly as glycogen in the liver and muscles. Because newborn liver and muscle masses are disproportionately smaller than those of an adult, infants are susceptible to hypoglycemia with risks for seizure and neurologic impairment. The minimum glucose infusion rate for neonates is 4 to 6 mg/kg/min. This rate must be calculated daily while the infant is receiving parenteral nutrition. For total parenteral nutrition (TPN), the glucose infusion rate is increased daily in increments of 1 to 2 mg/kg/min to a maximum value of 10 to 12 mg/kg/min. Hyperglycemia from a glucose infusion rate that is less than ideal should be avoided because it can lead to rapid hyperosmolarity and dehydration. Hyperglycemia may indicate underlying sepsis and should be appropriately investigated.

The average intake of protein is ~15% of the total daily calories and ranges from 2 to 3.5 g/kg/day in infants. This protein requirement is reduced in half by the age of 12 years and approaches the adult requirement (1 g/kg/day) by 18 years of age. The provision of greater amounts of protein relative to nonprotein calories will result in rising blood urea nitrogen levels. Thus, the non-protein (carbohydrate plus fat calories) to protein-calorie ratio (expressed in grams plus fat calories) is not less than 150 to 1. For infants receiving parenteral nutrition, protein administration usually starts at 0.5 g/kg/day and advances in daily increments of 0.5 g/kg/day to the target goal of approximately 3.5 g/kg/day.

Fat is another major source of nonprotein calories. Linoleic acid, an 18-carbon chain with two double bonds, is considered an essential fatty acid; its deficiency results in dryness, rash, and desquamation of skin. In pediatric patients, fat is provided as a major source of calories to prevent the development of essential fatty acid deficiency. The lipid requirements for growth are significant, and fat is a robust calorie source. Similar to protein, fat infusions are started at 0.5 g/kg/day and advanced up to 2.5 to 3.5 g/kg/day. In infants with unconjugated hyperbilirubinemia, fat is administered with caution because fatty acids may displace bilirubin from albumin. The free unconjugated bilirubin may then cross the blood-brain barrier and can lead to kernicterus, resulting in mental retardation.

TPN is reserved for infants for whom adequate daily enteral nutrition cannot be achieved. Infants have sufficient energy reserves to tolerate short periods of starvation lasting 2 to 3 days. Thus, an infant's need for parenteral nutrition should be addressed promptly. The total TPN infusion rate is kept at a steady-state rate to meet daily fluid requirements, and the concentration of nutrients is gradually increased daily until goals are met. Infants with surgical conditions often become cholestatic, typically caused by prolonged TPN support; however, other causes should be ruled out. Serum bile acid levels are usually elevated first, then direct bilirubin concentration, followed by liver enzyme levels. The ideal treatment for TPN-associated cholestasis is restoring enteral feeding. The use of omega-3 fat emulsion (Omegaven) has been critical in preventing TPN-induced cholestasis.[1] A medium-chain triglyceride–containing formula is used, and if an infant is receiving total enteral nutrition, fat-soluble vitamins should be supplemented.

HEAD AND NECK LESIONS

Subcutaneous Nodules

Benign subcutaneous nodules are quite common in pediatric patients of all ages. Dermoid and epidermoid cysts are benign lesions that arise from part of the dermal or epidermal tissues, forming a small cyst filled with normal skin components. Dermoid cysts may contain various dermal components, such as hair and skin glands. Epidermoid cysts typically have only epidermal tissue and keratin debris. They commonly occur on the forehead, lateral corner of the eyebrow, or anterior fontanelle or in the postauricular space. They are generally asymptomatic but may increase in size over time and can often become osteolytic. Most scalp lesions require only the clinical examination for diagnosis and subsequent surgical excision. Pilomatrixoma is another common, slow-growing benign skin tumor of the hair follicle. They often present as discrete and firm, nontender subcutaneous nodules but require surgical excision when presenting with symptoms of localized pain or infection. For midline lesions, an ultrasound examination can be valuable in delineating benign subcutaneous lesions from others, such as communicating cephalocele.

Lymphadenopathy

Enlarged lymph nodes present as mobile discrete solitary tumors or a cluster of tumors in the neck, axillary region, and groin. They typically are present along the sternocleidomastoid muscle border in the neck and over the inguinal canal and femoral triangle areas. Enlarged lymph nodes are one of the most common conditions for pediatric surgical consultation for evaluation, biopsy, or removal. The etiology is often unknown but presumed to be multifocal. A detailed history and physical examination are sufficient to determine whether surgery is indicated. The use of ultrasound has become widely prevalent and can, at times, identify nodes with central necrosis requiring immediate surgical intervention. Occasionally, lymph nodes presenting as fixed, nontender, progressively enlarging masses in the supraclavicular region should raise suspicion for malignancy. Constitutional symptoms such as night sweats and weight loss should prompt a thorough investigation; chest radiography could detect mediastinal adenopathy. Acute, bilateral cervical lymphadenitis from respiratory viral infectious causes (e.g., adenovirus, influenza virus, respiratory syncytial virus) requires observation alone. *S. aureus* and group A streptococcus are responsible for the majority of acute pyogenic lymphadenitis.

Cat-scratch disease is a self-limited infectious condition characterized by painful regional lymphadenopathy. A gram-negative bacillus, *Bartonella henselae,* is responsible for most cases. A history of exposure to cats is helpful but not always present. Indirect immunofluorescence antibody testing has only moderate specificity. Polymerase chain reaction assay of a lymph node biopsy specimen can increase diagnostic accuracy. Cat-scratch disease is usually self-limited. A less common infectious cause of cervical lymphadenitis is nontuberculous mycobacterial infection. The nodes are fluctuant, with a violaceous appearance of the overlying skin. The diagnosis is made by positive cultures for nontuberculous acid-fast bacilli, along with a tuberculin skin test. Surgical excision is usually indicated because most nontuberculous mycobacteria are resistant to conventional chemotherapy.

Cystic Hygroma

Cystic hygroma is a multiloculated cyst lined by endothelial cells, resulting from a lymphatic malformation. Most involve the lymphatic jugular sacs and are present in the posterior neck region. Other common sites are the axillary, mediastinal, inguinal, and retroperitoneal regions; approximately 50% of these cystic lesions are present at birth. Cystic hygromas are soft cystic masses that can distort the surrounding structure, including the airway. A large cystic mass of the neck in the fetus can pose a significant threat to the airway at birth. Prenatal ultrasound and fetal magnetic resonance imaging (MRI) studies can better demonstrate the extent of the disease along with its mass effect on the airway. If present, careful coordination of surgical intervention (ex utero intrapartum treatment [EXIT] procedure) at the time of delivery can be lifesaving, though this is more likely with solid tumors such as teratomas. Cystic hygromas are prone to infection and hemorrhage into the mass. MRI is useful in outlining the extent of lymphatic channels. The surgical goal is to complete surgical excision with tedious isolation and ligation of lymphatic branches. Aggressive blunt and electrocautery dissections as well as radical resection must be avoided, as this can lead to recurrence or infection due to incomplete control of lymphatics. When a complete surgical excision is not feasible, injection with sclerosing agents, such as bleomycin, doxycycline, or OK-432 derived from *Streptococcus pyogenes*, should be considered as an effective nonsurgical option.[2]

Thyroglossal Duct Cyst

An upper midline cystic neck lesion in toddlers is a thyroglossal duct cyst until proven otherwise (Fig. 117.1). It originates at the base of the tongue at the foramen cecum and descends through the central portion of the hyoid bone. Although thyroglossal duct cysts may occur anywhere from the base of the tongue to the thyroid gland, most are found at or just below the hyoid bone. A thyroid diverticulum develops as a median endodermal thickening at the foramen cecum in the embryonic stage of development. The thyroid diverticulum descends in the neck and remains attached to the base of the tongue by the thyroglossal duct. As the thyroid gland descends to its normal pretracheal position, the ventral cartilages of the second and third branchial arches form the hyoid bone. Hence, the intimate anatomic relationship of the thyroglossal duct remnant exists with the central portion of the hyoid bone. The thyroglossal duct normally regresses by the time the thyroid gland reaches its final position. When the elements of the duct persist despite complete thyroid descent, a thyroglossal duct cyst may develop. Failure of normal caudal migration of the thyroid gland results in a lingual thyroid, in which no other thyroid tissue is present in the neck. Ultrasound or radionuclide imaging may be useful to identify the presence of an ectopic thyroid gland in the neck. The Sistrunk procedure, first described in 1928, is the standard operation for thyroglossal duct cysts. It involves complete excision of the cyst in continuity with its tract, the central portion of the hyoid bone, and the tract interior to the hyoid bone extending to the base of the tongue. Incomplete resection can result in cyst recurrence in up to 40% to 50% of cases.

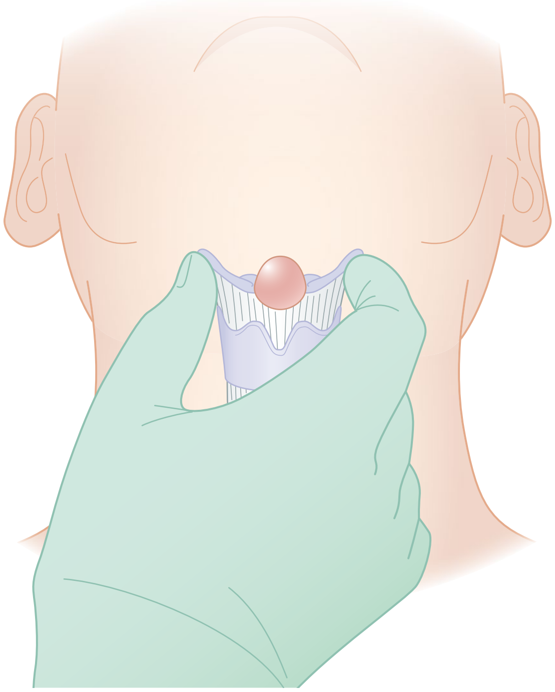

FIGURE 117.1 Thyroglossal duct cyst presents as a midline neck mass. A thyroglossal duct cyst can extend up to its origin at the foramen cecum. (Josephs MD. Thyroglossal duct cyst. In: Chung DH, Chen MK, eds. *Atlas of Pediatric Surgical Techniques*. Philadelphia: Elsevier Saunders; 2010:28-33.)

Branchial Cleft Remnants

Branchial cleft remnants present as lateral neck masses. Embryologically, the structures of the head and neck are derived from six pairs of branchial arches, their intervening clefts, and pouches. Congenital cysts, sinuses, or fistulas result from failure of these structures to regress, persisting in aberrant locations. The location of these remnants generally dictates their embryologic origin and guides the subsequent operative approach. Failure to understand the embryology may result in incomplete resection or injury to adjacent structures. Branchial lesions can manifest as sinuses, fistulas, or cartilaginous rests in infants. The clinical presentation ranges from continuous mucoid drainage, a fistula or sinus, or an infected cystic mass. Branchial remnants may also be palpable, as cartilaginous lumps or cords corresponding with a fistulous track. Dermal pits or skin tags may also be present. First branchial anomalies are typically located in the front or back of the ear or in the upper neck near the mandible. Fistulas typically course through the parotid gland, deep or through branches of the facial nerve, and end in the external auditory canal. The second branchial cleft anomalies are the most common type. The external ostium of these remnants is located along the anterior border of the sternocleidomastoid muscle, usually in the vicinity of the upper half to the lower third of the muscle. A tortuous and long course of the fistula tract can be found, which requires stepladder counterincisions in order to excise the fistula track completely. Typically, the fistula penetrates the platysma, ascends along the carotid sheath to the level of the hyoid bone, and turns medially to extend between the carotid artery bifurcations. The fistula courses adjacent to the hypoglossal and glossopharyngeal nerves, behind the posterior belly of the digastric and stylohyoid muscles, to end in the tonsillar fossa or other nasopharyngeal spaces. Third branchial cleft remnants usually do not have associated sinuses or fistulas. They are located in the suprasternal notch or clavicular region and can descend into the mediastinum. They present more commonly as cysts in toddlers and older children. These often contain cartilage and present clinically as a firm mass or subcutaneous abscess.

DIAPHRAGMATIC CONDITIONS

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a spectrum of developmental conditions marked by a diaphragmatic defect, causing

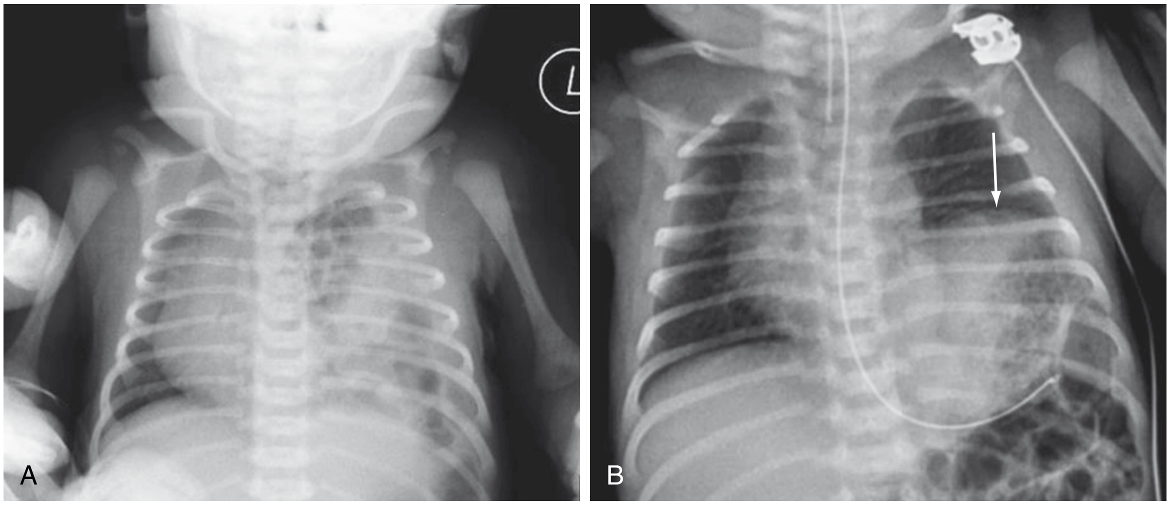

FIGURE 117.2 (A) Congenital diaphragmatic hernia. Multiple gas-filled bowel loops are located in the left hemithorax, and the mediastinum is shifted to the right. (B) Left diaphragmatic eventration. Hemidiaphragm is elevated *(arrow)* from phrenic nerve injury-induced paralysis.

abdominal contents to protrude into the thoracic cavity, disrupting lung and pulmonary vascular development (Fig. 117.2A). These anomalies range from a small opening in the posterior muscle rim to the complete absence or agenesis of the diaphragm. In most cases this is unilateral but rarely may be bilateral. This may lead to varying degrees of lung hypoplasia and pulmonary hypertension in the newborn that may significantly impact short-term survival and long-term morbidity. Advances in research and therapeutics over the last few decades have led to improved survival outcomes of 65% to 90%.[3–5]

The overall incidence of CDH is variably reported at ~1:2000 to 5000 childbirths, with most cases sporadic, isolated, and nonsyndromic. Although the exact etiology is unknown, animal models suggest genetic, environmental, and nutritional factors.[3] The diaphragm is embryologically derived from the septum transversum, the pleuroperitoneal folds, components of the abdominal wall, and the dorsal mesentery. At 3 to 4 weeks of gestation, these structures begin to fuse, separating the pleural and peritoneal cavities. This is followed by ingrowth from the abdominal wall, creating the muscular component of the diaphragm; this is typically complete by 9 weeks of gestation. Incomplete fusion may lead to an anterior defect or Morgagni hernia (~23%–28%), central hernia (2%–7%), or most commonly, Bochdalek posterior lateral hernia (70%–75%). Bochdalek hernias occur most commonly on the left side (85%) and less on the right side (13%) or rarely bilaterally (2%).[3] Abdominal contents herniate into the thoracic cavity through the diaphragmatic defect, compressing the ipsilateral developing lung. These lungs have smaller bronchi, with less bronchial branching and less alveolar surface areas. The ipsilateral lung is affected more severely; however, both lungs are affected by pulmonary hypoplasia. In addition, the pulmonary vasculature is significantly affected by increased thickness of the arteriolar smooth muscle. Arteriolar vasculature is also extremely sensitive to local and systemic vasoactive factors. The severity of pulmonary hypoplasia and pulmonary hypertension significantly impacts overall morbidity and mortality in infants with CDH.

Clinical Presentation

Routine utilization of prenatal ultrasound has led to diagnosis as early as 15 weeks of gestation, especially in very large defects. Sonography at 22 to 24 weeks may demonstrate mediastinal shift, juxta-cardiac gastric dilatation, polyhydramnios, or other congenital anomalies. In the less common right-sided CDH, the liver may be seen in the right chest. The sonographic measurements of the lung size may establish important prognostic criteria helpful in prenatal and postnatal therapeutic management. The major predictors of outcome on fetal evaluation include the presence of coexistent congenital anomalies such as cardiac, chromosomal abnormalities, lung hypoplasia, and intrathoracic liver herniation.[6]

Lung head ratio (LHR) is a sonographic assessment of fetal lung size made by comparing the contralateral lung to head circumference with normal gestational age measurement. This quotient of the observed to expected size for gestational age may be a useful predictor of early neonatal morbidity. At birth, most infants with CDH may experience respiratory distress manifested by grunting, dyspnea, retractions, and cyanosis, although delayed presentations may occur. The physical examination may be notable for a scaphoid abdomen with diminished breath sounds in conjunction with bowel sounds in the chest. There may also be displacement of heart tones (depending on the side of the hernia). Pulse oximetry may demonstrate significant preductal and postductal differences indicative of right-to-left shunting, which is an important factor in management and prognosis. Chest x-ray indicating intrathoracic bowel loops and mediastinal shift may occur. In 10% to 20% of cases, CDH is diagnosed after the first 24 hours of life, typically when infants present with feeding difficulties, respiratory distress, or pneumonia. In Morgagni hernias, the diagnosis is often delayed until childhood because most infants are asymptomatic.[3]

Management

Intrauterine treatment of CDH with fetal endoluminal tracheal occlusion (FETO) may play a role in the management of patients with severe pulmonary hypoplasia secondary to diaphragmatic hernia. This technique involves endoscopic in utero balloon placement to occlude the trachea typically between 27 and 29 weeks of gestation followed by interval balloon retrieval a few weeks later. This leads to increased lung fluid retention and subsequent lung growth. Although this treatment is limited to a few centers, results are promising. A meta-analysis of studies indicate FETO may reduce pulmonary hypertension, extracorporeal membrane oxygenation (ECMO) utilization, and mortality.[7] A recent multicenter European randomized controlled trial, Tracheal Occlusion to Accelerate Lung Growth (TOTAL), has demonstrated significant survival benefit at discharge and 6 months of age.[8] Complications include preterm labor, premature rupture of membranes, premature birth, and fetal demise. The evolution of fetal surgery and its clinical applications are discussed in Chapter 118.

The mainstay of initial CDH management focuses on aggressive treatment of pulmonary hypertension by airway stabilization, GI decompression, barotrauma limitation ("gentilation"), permissive hypercapnia, and meticulous hemodynamic monitoring while minimizing iatrogenic injury. High-volume centers with protocolized care have been found to have enhanced outcomes. Other interventions such as nitric oxide, high-frequency oscillatory ventilation, and ECMO have demonstrated effectiveness in stabilizing and treating worsening pulmonary hypertension. Various agents to reduce pulmonary hypertension such as prostaglandin (PGE1), prostacyclin (PGI2), sildenafil, a phosphodiesterase-5 inhibitor, and milrinone may have benefits in select cases, but most of these are not FDA approved.[8]

Surgical Repair

Optimal timing of CDH repair in infants who have no cardiopulmonary instability and are not on ECMO should likely be deferred 48 to 72 hours to limit risks of pulmonary vascular lability induced by surgical stress. Controversy remains regarding the optimal (ideal) timing of CDH repair in patients on ECMO, with some proponents supporting repair during ECMO and others strongly advocating for repair at the time of weaning or after decannulation. There is no prospective randomized data available to support either approach. Bleeding complications are significantly higher in patients repaired on ECMO, requiring attention to hemostasis. A recent report suggested that early CDH repair during ECMO therapy is associated with improved survival compared with repair later in the ECMO course when azotemia increases risks for bleeding.[9]

Although open and laparoscopic repair are both feasible options, there is no clear data on the optimum approach or long-term outcomes. Repair of a posterolateral CDH is usually performed through an ipsilateral subcostal abdominal incision with excision of the hernia sac, if present. This is followed by a reduction of intrathoracic visceral contents into the abdomen. Identification and mobilization of the anterior medial leaflet facilitates tension-free closure of the posterolateral diaphragmatic defect with interrupted nonabsorbable sutures, sometimes with Teflon pledgets. Although primary repair is preferred, some hernia defects may be large and require various reconstructive techniques, including the use of rectus abdominus or latissimus dorsi muscle flaps or alternatively prosthetic materials to achieve repair. Gore-Tex patch prostheses are most widely used; however, the use of regenerative extracellular matrix biomaterials (e.g., Surgisis) that are biodegradable may have utility. The advantages of prosthetic patches are that they offer shorter operative time and a tension-free repair.

In general, thoracostomy tube placement is unnecessary, especially if postoperative radiographs demonstrate immediate mediastinal shift toward the midline. Repair of the diaphragmatic hernia with reduction of the viscera may lead to the loss of abdominal domain and impending abdominal compartment syndrome requiring temporary abdominal silo placement with interval abdominal wall closure. Alternatively, skin-only closure with a resultant incisional hernia followed by delayed definitive fascial closure may be an option to consider. Prosthetic patch abdominoplasty is also a viable approach.

Long-term outcomes in infants with CDH vary. Some may develop a chronic condition due to PPHN and respiratory dysfunction. Moreover, infants who receive aggressive and prolonged care in the neonatal intensive care unit have a high incidence of developmental delay, seizures, and hearing loss. Other morbidities for CDH survivors include chronic lung disease, scoliosis, growth retardation, pectus excavatum deformities, gastroesophageal reflux (GER) disease, and foregut dysmotility.

Eventration of Diaphragm

Abnormal elevation of the hemidiaphragm (eventration) seen on chest radiograms can significantly affect respiratory function, leading to tachypnea, discordant breathing, and respiratory embarrassment. Eventration of the diaphragm can be congenital or acquired. Congenital eventration typically occurs due to birth trauma (Erb palsy) or secondary to an anatomic abnormality of the diaphragm. Erb palsy is paralysis of the arm caused by brachial plexus injury following a difficult or traumatic delivery due to shoulder dystocia. Injury to the ventral rami of spinal nerves C5 through C8 commonly includes ipsilateral diaphragmatic paralysis due to traction injury of the phrenic nerves and upper portion of the brachial plexus. Acquired eventrations are usually secondary to iatrogenic phrenic nerve injury during open cardiac surgery. Elevation of the diaphragm can be visualized on chest radiographs (see Fig. 117.2B); however, it can easily be misdiagnosed as CDH. The diagnosis is confirmed by dynamic visualization of the diaphragm using either fluoroscopy or ultrasound of the chest. Absent or paradoxical movement of the diaphragm on inspiration is diagnostic of eventration. When symptoms progress, resulting in respiratory distress or inability to wean from ventilatory support, repair is indicated. The surgical treatment of diaphragm eventration is an open or laparoscopic diaphragm plication in which the diaphragm is securely folded using multiple interrupted nonabsorbable sutures.

BRONCHOPULMONARY MALFORMATIONS

Bronchopulmonary malformations are congenital abnormalities of the airway and include bronchogenic cysts, intralobar and extralobar sequestrations (ELSs), cystic pulmonary adenomatous malformations (CPAMs), and congenital lobar emphysema (CLE). In the perinatal period, these lung lesions can result in pleural effusions, polyhydramnios, hydrops, and pulmonary hypoplasia with subsequent respiratory distress and even airway obstruction. If severe enough, fetal demise can occur. Most of these lesions are diagnosed prenatally with ultrasound. Fetal surgery has been pursued when fetal viability is at risk. After birth, congenital lung lesions are often asymptomatic, and some may even spontaneously regress. However, there is concern that some lesions may lead to recurrent pulmonary infections and exhibit long-term malignant potential.

Cystic Pulmonary Adenomatous Malformation

The most frequently diagnosed congenital lung anomaly is CPAM, a multicystic dysplastic lesion that displaces normal lung tissue. It occurs with an incidence of about 1 per 25,000 to 35,000 live births. CPAMs are hamartomatous lesions that arise during the early pseudoglandular phase of lung development from aberrant morphogenesis secondary to proximal airway obstruction that induces terminal bronchial overgrowth. CPAM communicates with the tracheobronchial tree and adjacent lung tissue and receives pulmonary blood supply. Frequently diagnosed in utero by ultrasound or fetal MRI, many prenatal CPAMs will undergo partial regression during the third trimester. Postnatal diagnosis is often made following a chest x-ray demonstrating large cystic lung lesions and/or pneumothorax performed for a patient with respiratory symptoms. Ultrasound, CT, and MRI may confirm these findings, which may also be seen in sequestration or diaphragmatic hernia.[10]

The majority of CPAMs are asymptomatic in utero and during infancy, and can be managed expectantly. Antenatal treatment with betamethasone has been effective in inducing spontaneous involution, size decrease, and hydrops amelioration. Rarely, CPAMs cause fetal distress and demise secondary to compressive effects and hydrops. These patients may be candidates for in utero intervention or fetal surgery. At birth, some patients may present with varying degrees of respiratory distress from tachypnea, grunting, and oxygen requirement. Severe life-threatening respiratory distress secondary to pulmonary hypoplasia, lung compression, and/or mediastinal displacement that occurs at birth requires emergency surgical resection and/or ECMO. In older children and adults CPAM may present with recurrent pneumonia, pneumothorax, hemoptysis, respiratory distress, or lung abscess.

Classification of CPAMs is typically based on the imaging criteria and pathologic confirmation. Historically, these congenital lung anomalies were classified by Stocker classification as type I (macrocystic), type II (mixed), and type III (solid/microcystic).[11] Although this descriptive approach was useful for the assessment of prenatal lung lesions, it was insufficient as a postnatal diagnostic and prognostic tool. Modification of the Stocker classification now categorizes CPAM into five different types (Type 0–IV), based on the origin of the tracheobronchial tree, the presence of cystic components, radiologic appearance, and dimensions. This newer classification system has greater diagnostic, therapeutic, and prognostic utility. Resection is recommended in all patients who do not undergo spontaneous regression to minimize the risk of complications, to enhance lung growth and decrease the risk of malignant transformation. Surgical resection is recommended within the first 2 years of life.[12]

Bronchopulmonary Sequestration

Bronchopulmonary sequestration is a dysplastic segment or lobe of nonfunctional lung tissue that lacks communication with the tracheobronchial tree and receives a systemic (nonpulmonary) blood supply. These lesions account for <6% of all congenital lung anomalies. Two variants of sequestration exist: intralobar (ILS) and ELS. The intralobar variant is embedded within the visceral pleura of the normal lung parenchyma. It has venous drainage into the pulmonary venous system but receives systemic arterial blood supply. ILS is primarily found in the lower lobe with two-thirds located in the posterior basal segment. They are three times more common than extralobar variants. In contrast, ELSs have a separate visceral pleura, systemic venous drainage, and arterial supply. They are often located between the diaphragm and lower lobes but may rarely occur in infradiaphragmatic and retroperitoneal locations. ELS may be associated with other congenital anomalies, such as posterolateral diaphragmatic hernia, pectus excavatum and carinatum, and enteric duplication cysts. ILS may remain asymptomatic even into adulthood and is often diagnosed incidentally on chest CT scans in patients without symptoms. However, the most frequent clinical presentation is recurrent pneumonia in a specific lung segment. Other potential symptoms include a persistent cough, hemoptysis, back pain, or exertional shortness of breath.

ELSs do not form enlarged cysts or cause spontaneous pneumothoraces due to lack of communication to the airway. They can, however, infarct, become infected, and cause hemoptysis. It has been reported that ELSs can undergo torsion as well. Anomalous systemic vascular supply may lead to significant left-to-right shunting in neonates that may increase susceptibility to high-output cardiac failure.

Pulmonary sequestrations may be diagnosed on routine prenatal ultrasound. In the absence of other findings, the fetus is observed with serial ultrasound monitoring for enlargement and potential pleural effusion, polyhydramnios, or hydrops. Spontaneous regression has been reported in more than two-thirds of prenatally diagnosed lesions, possibly related to the outgrowth of the blood supply. Initial evaluation at birth of a known sequestration may include Doppler ultrasound to assess the nature of the lesion (cystic or solid) and the anatomy of the systemic arterial supply from the infradiaphragmatic or thoracic aorta. CT or MRI may aid in further definition of the vascular and structural anatomy but is not indicated in a stable patient with an ultrasound that is not worrisome. ELSs are often asymptomatic due to the absence of airway communication. The presence of air or an air-fluid level rarely indicates fistulous connection to the GI tract. Surgical management of these lesions is performed via standard open or thoracoscopic segmentectomy or lobectomy for ILS, and mass resection for ELS.

Congenital Lobar Emphysema

CLE is a developmental anomaly of the lung that may be characterized by respiratory distress due to hyperinflation of one or more pulmonary lobes inducing compression of adjacent lung parenchyma. The incidence is ~1:20,000 to 30,000 live births with a 3:1 male predominance primarily present in the first 6 months of life and rarely in adults. Various etiologies may contribute to the pathogenesis, including intrinsic bronchial cartilaginous abnormalities leading to stenosis, atresia, or bronchomalacia. Alternatively, extrinsic conditions such as aberrant blood vessels or masses may lead to bronchial abnormalities inducing lobar emphysema. The left upper lobe is most affected (~43%) followed by the right middle lobe (32%) and right upper lobe (21%). This air trapping or hyperinflation may be secondary to abnormalities in bronchial cartilages or parenchymal disease (polyalveolar lobe) with expiratory collapse of the bronchus. The affected lobe is essentially nonfunctional because of overdistention and air trapping in the lung during the expiratory phase of respiration due to deficient bronchial cartilage, which causes repeated episodes of respiratory distress. It is frequently recognized in newborns; however, a few cases do not present until adulthood. This disease is potentially reversible if diagnosed and treated timely. A chest radiograph is generally diagnostic, revealing overdistention of the involved lobe. Importantly, the lucency should not be mistaken for a pneumothorax. Positive pressure ventilation should be used with caution, as these patients are prone to developing auto–positive end-expiratory pressure, which refers to the end-expiratory intrapulmonary pressure that develops due to dynamic airflow resistance during mechanical ventilation. When the CLE progresses to cause a mediastinal shift and worsening respiratory symptoms, an expeditiously performed open lobectomy is indicated.

Bronchogenic Cysts

Bronchogenic cysts are foregut-derived pulmonary malformations that arise from abnormal budding of the lung or the tracheobronchial tree during the embryonic and early pseudoglandular stages of lung morphogenesis (third through sixth weeks of gestation). Subsequent differentiation into a fluid-filled, blind-ending pouch leads to the development of this cystic structure. The location of a bronchogenic cyst depends on the embryologic stage of development at which the anomaly occurs. When the abnormal budding happens during early development, the cyst occurs along the tracheobronchial tree with a high prevalence near the carina and right hilum. Cysts that arise later are more peripheral and may involve the lung parenchyma.

The wall of bronchogenic cysts consists of fibroelastic tissue, smooth muscle, and cartilage. They are lined with respiratory tract ciliated columnar epithelial cells and can contain mucus-producing cuboidal cells, which may contribute to cyst enlargement due to mucus accumulation. Enlargement may lead to airway compression or displacement of other intrathoracic structures. This poses a higher risk in infants due to their narrow and easily compressible trachea and bronchus. Symptoms associated with bronchogenic cysts include dysphagia, pneumothorax, cough, hemoptysis, and, in cases of late presentation, infection.

These lesions are rare, with a reported incidence of 1:42,000 to 68,000 and a male predominance. Many may remain undiagnosed until adulthood. Diagnosis of bronchogenic cysts is often suspected based on routine chest radiographs and confirmed using a CT scan. CT scans reveal a nonenhancing, mucus-filled cystic mass with a spherical appearance. If the cyst communicates with the airway, an air-fluid level may be visible. Cysts located within the pulmonary parenchyma typically communicate with a bronchus, whereas mediastinal cysts usually do not. Surgical resection is the recommended treatment for bronchogenic cysts, irrespective of symptoms. This involves the complete removal of the cyst. Although rare, cases of malignant transformation have been reported.

ALIMENTARY TRACT CONDITIONS

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (EA) represents a congenital interruption of the esophageal continuity leading to proximal esophageal obstruction. Concurrently, a tracheoesophageal fistula (TEF) is a pathologic communication between the esophagus and trachea. These malformations can manifest independently or in conjunction. They present in 1 of 1500 to 3000 live births, displaying a mild male predilection. Approximately 33% of affected neonates have a diminished birth weight, and associated anomalies are evident in 60% to 70%.

During the fourth gestational week, incomplete division of the esophagotracheal diverticulum of the foregut leads to the previously mentioned defects. A subset of 10% exhibits a nonrandom, nongenetic aggregation of anomalies characterized as VATERL (vertebral, anorectal, tracheal, esophageal, renal, and radial limb). Five anatomic EA variants are detailed in Fig. 117.3. The prevalent type (C lesion) features proximal EA and distal TEF; the proximal blind pouch concludes roughly at a distance equivalent to one or two vertebral bodies from the distal TEF. The TEF is typically proximal to the carina in the trachea's membranous segment.

Clinical suspicion for EA arises in neonates presenting excessive salivation and initial feeding-associated coughing or choking. The retraction or failure to pass an orogastric tube at the thoracic inlet is a defining feature of EA with or without TEF. Maternal polyhydramnios is recurrent, particularly prominent in isolated proximal atresia (86%). Neonates with proximal EA and distal TEF may manifest acute gastric distention due to inspiratory air influx into the distal esophagus and stomach. Reflux into the distal esophagus allows gastric contents to breach the TEF, culminating in symptoms such as cough, tachypnea, apnea, or cyanosis. Isolated TEF, in the absence of EA, might present subtly, often postneonatally. Typically, these neonates display feeding-induced choking and coughing. Failure to introduce an orogastric tube into the stomach is a diagnostic hallmark of EA with a chest radiograph revealing a recoiled orogastric tube in the proximal esophagus confirming the diagnosis (Fig. 117.4A). The presence of intra-abdominal gas confirms TEF. However, an infant demonstrating absent GI air radiographically after failing a nasogastric tube insertion is likely suffering from isolated EA. An oral contrast study is contraindicated due to aspiration risks. Echocardiography and renal ultrasonography are imperative for assessing congenital heart and genitourinary defects, respectively.

To decompress the proximal esophageal pouch, a continuous suction-applied sump tube is introduced. Infants are optimally positioned upright prone to mitigate aspiration of saliva. Broad-spectrum intravenous (IV) antibiotics are initiated. Endotracheal intubation is generally eschewed, as positive pressure ventilation may inadequately inflate the lungs; air might preferentially navigate into the GI tract via the TEF. Ventilation can further be jeopardized by significant gastric distention. In this scenario,

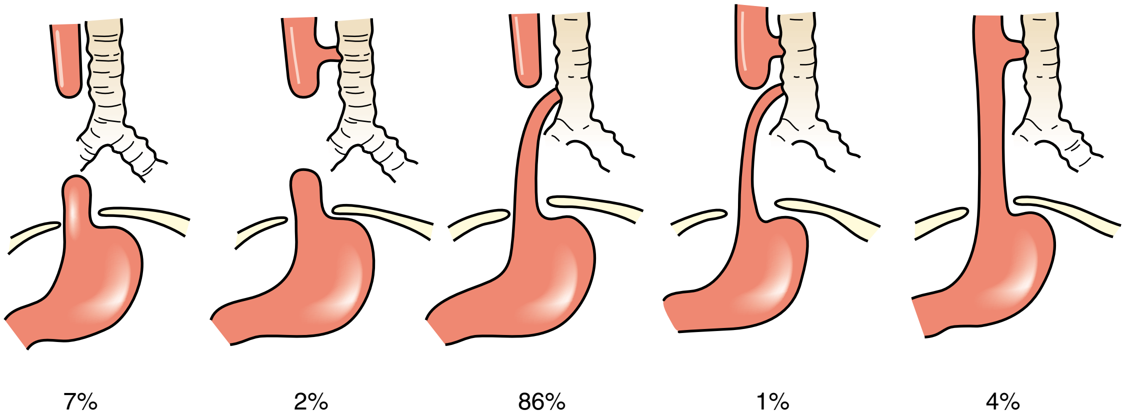

FIGURE 117.3 Anatomic variants and incidence of esophageal atresia with tracheoesophageal fistula.

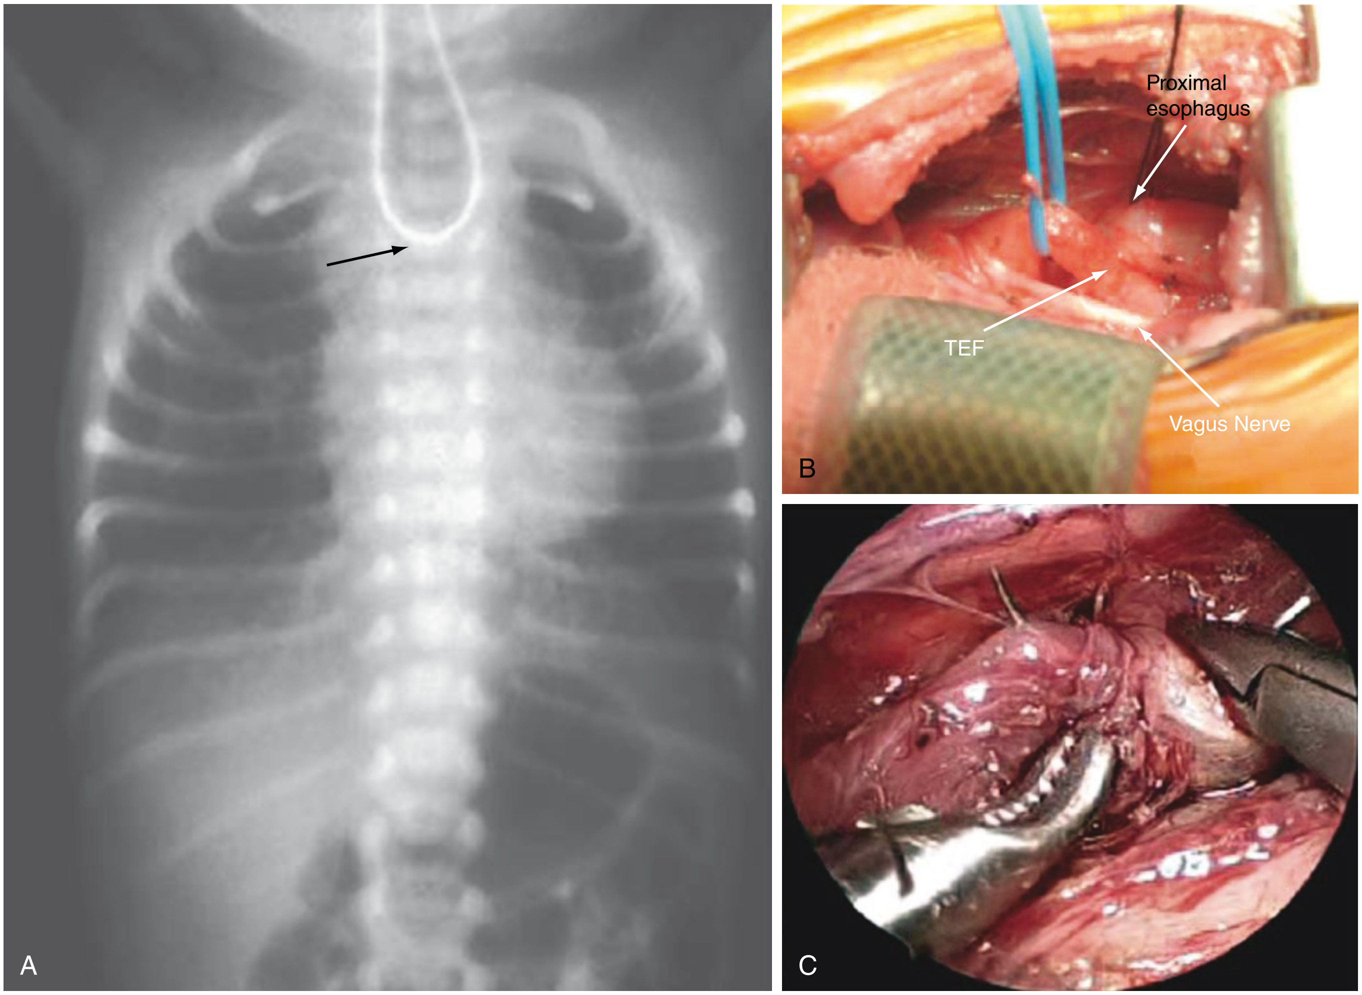

FIGURE 117.4 (A) Plain chest radiograph of infant with proximal esophageal atresia with distal tracheoesophageal fistula. The distal tip of the orogastric tube is curled up at the level of thoracic inlet *(arrow)*. (B) Distal tracheoesophageal fistula *(TEF; arrow)* is encircled with a blue vessel loop. Proximal blind esophageal pouch is in close proximity *(arrow)*. (C) Thoracoscopic esophageal anastomosis. Interrupted sutures are placed using intracorporeal technique.

prompt recognition and management is necessary to save the patient. Moving the endotracheal tube distally past the TEF or utilizing an occlusive balloon catheter in the fistula can improve ventilation. Emergent thoracotomy with fistula ligation may be necessary. In extreme cases, emergent gastrostomy is necessary to decompress the stomach and improve ventilation. The gastrostomy tube can be placed to water seal, similar to a tube thoracostomy, to facilitate ventilation while allowing the air traveling through the TEF to escape. Preoperative chest radiographs and echocardiograms are adequate to elucidate aortic arch anatomy. Right thoracotomy is favored for operative repairs in patients with a conventional left-sided aortic arch. For patients with a right-sided arch, left and right thoracotomy may be used, based on surgeon preference. A right-sided aortic arch exhibits an increased incidence of arch anomalies and postoperative complications.

The classic surgical approach for the proximal EA and distal TEF (C type) is an extrapleural dissection through open thoracotomy. Currently, a minimally invasive approach is most common. Initial rigid bronchoscopy allows for evaluation of the degree of tracheomalacia and the anatomic location of the TEF, but some surgeons consider it optional for excluding a secondary fistula due to its low detection yield. However, for recurrent fistulas, bronchoscopic evaluations with Fogarty catheter placement delineates the anatomy, facilitating safer dissection. The subsequent step involves thoracotomy with extrapleural dissection and division of the azygos vein, revealing the underlying TEF. The tracheal defect is closed by sequentially dividing a 1- to 2-mm segment of the fistula and immediately closing the defect using absorbable interrupted sutures to prevent loss of ventilation of the patient. The upper esophageal pouch is then maximally mobilized to enable tension-free esophageal anastomosis. The vasculature of this pouch is typically robust, whereas the lower pouch exhibits a more segmental and precarious supply, urging limited mobilization to avoid ischemia (see Fig. 117.4B). The anastomosis can be executed using single- or double-layer techniques. The thoracoscopic approach (see Fig. 117.4C) is increasingly preferred with favorable outcomes.

For cases of long-gap EA, several methodologies exist to secure additional length for primary anastomosis. Although esophagomyotomy of the upper pouch was previously employed, the resultant esophageal dysmotility has led to its obsolescence. An alternative involves suturing the distal esophagus' divided closed end to the prevertebral fascia, marking it with a hemoclip. As the infant grows, this facilitates esophageal lengthening for subsequent primary anastomosis. Neonates with pure EA necessitate gastrostomy for enteral feeding, as primary anastomosis is not feasible during the neonatal phase. Current practices involve managing secretions with an indwelling orogastric tube. Once adequate esophageal elongation is confirmed radiographically (Fig. 117.5), primary anastomosis can be attempted, typically around 4 to 6 months of age. In some cases, cervical esophagostomy is performed when continued aspiration occurs, and oral secretions cannot be managed by nasogastric tube drainage. In these cases, esophageal replacement using stomach, colon, or small intestinal conduit is performed at approximately 1 to 2 years of age. For isolated TEF cases, surgical intervention—typically near the thoracic inlet—is performed through a cervical incision. Rigid bronchoscopy and TEF guidewire cannulation can aid the dissection.

The mortality rate is intimately linked to concomitant anomalies, especially cardiac defects and chromosomal aberrations. The Spitz classification system is a risk stratification tool specifically developed to determine the prognosis of infants with EA and TEF. The system is based on the infant's birth weight and the presence or absence of major cardiac anomalies, as these two factors have been shown to significantly influence survival outcomes. Infants with a birth weight >1500 g and no major cardiac anomaly had a survival rate of 97%. Infants with either a birth weight of <1500 g or a major cardiac anomaly had a survival rate of 59%. Infants with a birth weight <1500 g and a major cardiac anomaly had a survival rate of 22%. Postoperative sequela might encompass esophageal motility disorders, GER (25%–50%), anastomotic stricture (15%–30%), anastomotic leak (10%–20%), and tracheomalacia (8%–15%).

Gastroesophageal Reflux

In neonates and infants, transient episodes of vomiting can often be attributed to an immature lower esophageal sphincter, a phenomenon typically resolving between 6 and 12 months of age. Persistent and severe GER can lead to notable complications such as failure to thrive due to caloric deprivation. Furthermore, aspiration of gastric contents may predispose to recurrent bronchitis or pneumonia, culminating in persistent respiratory symptoms. Vagal reflex stimulation due to reflux can result in laryngospasm or bronchospasm, manifesting in an asthma-like presentation.[13] Notably, reflux-induced airway spasms can lead to episodes of apnea or choking, which might be implicated in sudden infant death syndrome events. Chronic exposure of the lower esophagus to acid can predispose to stricture formation, presenting as obstructive symptoms, or even progress to Barrett esophagus. This metaplastic change from squamous to columnar epithelium mandates periodic surveillance due to the potential for dysplastic changes. Patients with neurodevelopmental disabilities occasionally necessitate enduring feeding modalities, such as gastrostomies. However, prophylactic fundoplication in this cohort, particularly due to potential airway protection deficits, is controversial.

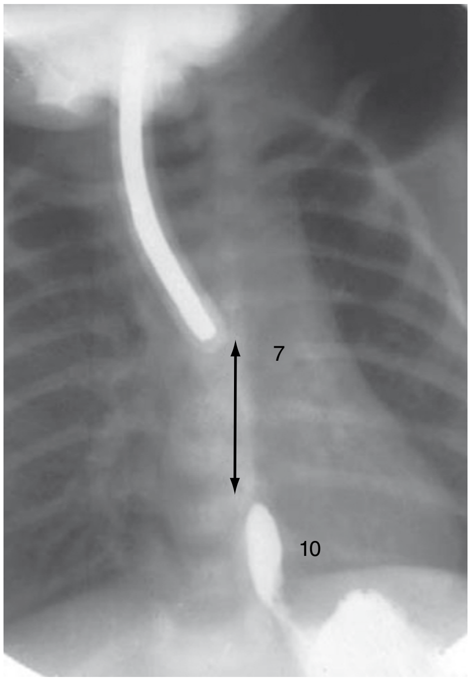

FIGURE 117.5 Contrast study per gastrostomy with an indwelling radiopaque orogastric tube. For pure atresia, the esophageal gap is assessed using this technique for either primary esophageal anastomosis or partial colonic segmental interposition.

Diagnostic modalities such as contrast esophagogram and upper GI are instrumental in procuring anatomic and functional insights, such as gastroduodenal motility aberrations. In addition, mechanical etiologies like esophageal strictures, antral webs, duodenal webs, or intestinal malrotation can be identified. A notable limitation is the modality's lack of specificity.

A 24-hour esophageal pH probe study remains the gold standard for the diagnosis of pathologic GER. It measures the frequency and duration of acid reflux episodes, along with patterns such as the total duration and the longest continuous episode. A combined multichannel intraluminal impedance pH test, in which reflux is detected by changes in intraluminal resistance determined by the presence of liquid or gas and pH changes, is a more comprehensive test. A gastric emptying scan can be obtained using a radionuclide-labeled (technetium-99m [^{99m}Tc] sulfur colloid) liquid or semi-solid food to quantitatively assess gastric emptying; ~50% of the isotope-labeled meal is normally emptied from the stomach within 60 minutes and nearly 80% by 90 minutes. Although pH and impedance studies are gaining in popularity, there are no widely accepted criteria for physiologic or pathologic reflux episodes, limiting its widespread use. Esophageal manometry measures the pressures of the esophageal body and lower esophageal sphincter. Manometry is not used regularly in pediatrics. Children with poor esophageal motility are prone to experience significant dysphagia after fundoplication with a complete wrap. In many cases, clinical evaluation of tolerance to nasogastric gavage feeding might suffice to determine whether significant reflux exists. Endoscopic assessments facilitate direct and histologic evaluation of the esophageal mucosa, revealing GER-induced mucosal injury. Concurrently, they aid in diagnosing eosinophilic esophagitis, an inflammatory condition increasingly recognized in the pediatric demographic that can mimic GER disease.

The primary line of GER management in pediatrics involves dietary modifications such as formula thickening, volume reductions, and positional adjustments. Pharmacologic interventions focusing on acid suppression are commonly employed. Surgical interventions, specifically fundoplication, are reserved for critical manifestations like life-threatening events, failure to thrive, or esophageal stricture. A Nissen fundoplication, entailing a 360-degree esophageal wrap, stands as the gold standard surgical modality for pediatric GER. Though highly efficacious in symptom mitigation, it may predispose to side effects like bloating or dysphagia. In recent years, advocates of Nissen fundoplication have suggested limited dissection of the hiatus and crura to limit complications. Alternatively, partial wraps, such as Toupet (270 degrees) or Thal (180 degrees), present fewer complications but might be less efficacious. The laparoscopic technique has emerged as the standard surgical approach for fundoplication.

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis (HPS) is a disease of newborns, with an incidence of 1 in 300 to 900 live births. It is most common between the ages of 2 and 8 weeks. Male infants are affected four times more often than females, with first-born male infants at the highest risk. Hypertrophy of the circular muscle of the pylorus results in constriction and obstruction of the gastric outlet. Although the exact cause of HPS remains unknown, a lack of nitric oxide synthase in pyloric tissue has been implicated.

Infants present with progressively worsening, nonbilious emesis that is projectile in nature. Visible gastric peristalsis may occasionally be observed as a wave of contractions from the left upper quadrant to the epigastrium. After emesis, infants still crave feeding. A plain abdominal radiograph can show an enlarged gastric gas bubble. Palpation of the pyloric “olive” tumor in the epigastrium by an experienced examiner is pathognomonic for HPS. If the olive is palpated, no imaging study is required for diagnosis. Today, most infants suspected of having HPS are evaluated with an ultrasound study before surgical consult. Pyloric muscle thickness of more than 3 to 4 mm or length of more than 15 to 18 mm on ultrasound in the presence of functional gastric outlet obstruction is diagnostic. If the clinical presentation is equivocal, an upper GI contrast study may be considered to demonstrate a lack of passage of contrast past the pylorus. However, it should be used with great caution as infants are at highest risk for aspiration. The upper GI study can also evaluate for other potential causes of emesis.

Preoperatively, resuscitation and correction of electrolyte abnormalities are essential. The infant must be resuscitated aggressively with IV fluids to establish an adequate urine output to restore acid-base balance. Initially, the infant should receive a bolus of 20 mL/kg of NS. Once urine output has been demonstrated, the maintenance IV fluids of D5 ½ NS with 20 mEq/L of potassium should be started at 1.5 times the maintenance rate. Loss of hydrochloric acid secondary to persistent emesis leads to hypokalemic, hypochloremic, metabolic alkalosis, and dehydration. In response, carbon dioxide and water are converted to hydrogen ion and bicarbonate ion to attempt to correct the electrolyte losses, resulting in a significant drop in carbon dioxide levels. If the patient is placed under anesthesia before correction of the electrolytes, postoperative apnea can occur due to the lack of respiratory drive from low carbon dioxide levels. Thus, the serum bicarbonate level and chloride level should be normalized to a value of less than 30 mEq/L and greater than 95 mEq/L, respectively. A pyloromyotomy (Ramstedt-Fredet procedure) involves incising the thickened pyloric musculature to relieve the pyloric channel obstruction. It is performed via a laparoscopic or open approach through various surgical incisions. A laparoscopic approach is used more routinely and can result in a shorter length of stay and a lower incidence of surgical site infection. Importantly, the fundamental surgical principle of pyloromyotomy is adequate cutting of hypertrophied pyloric muscle to achieve bulging mucosa and independent wall motion without mucosal injury (Fig. 117.6). Postoperatively, infants are managed on a feeding protocol clinical pathway, which ranges from immediate full ad lib feedings to incremental advancement with similar time to full feed and hospital discharge. Postoperative emesis is common, but it is self-limited. Full-thickness mucosal perforation occurs more commonly with a laparoscopic approach, but its incidence is still rare (<1%). However, when infants experience persistent emesis beyond 7 to 14 postoperative days, an upper GI contrast study is warranted to evaluate for incomplete pyloromyotomy.

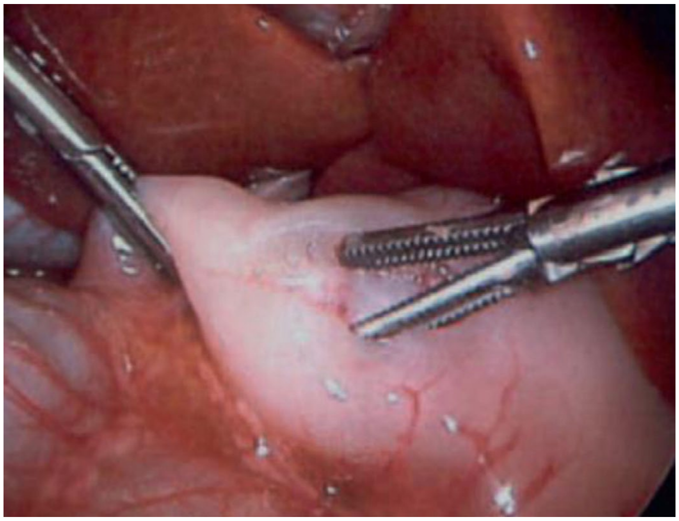

FIGURE 117.6 Laparoscopic pyloromyotomy is started with a retractable blade or Bovie cautery, and a spreader with grooves on the outer surface is used to perform the pyloromyotomy. Intact mucosal bulging along with independent muscle wall motion is confirmed. (From St. Peter SD, Ostlie DJ. Laparoscopic and open pyloromyotomy. In: Chung DH, Chen MK, ed. *Atlas of Pediatric Surgical Techniques*. Philadelphia: Elsevier Saunders; 2010:253-265.)

Intestinal Atresia

Duodenal atresia is thought to result from failure of recanalization of the duodenum from its solid cord stage. The range of anatomic variants includes duodenal stenosis, a mucosal web with intact muscle wall (so-called windsock deformity), two ends separated by a fibrous cord, and a complete separation with a resultant gap within the duodenum. It is associated with several conditions, including prematurity, Down syndrome, maternal polyhydramnios, malrotation, preduodenal portal vein, annular pancreas, and biliary atresia (BA). Other anomalies, such as cardiac, renal, EA, and anorectal malformations, are also common. In most cases, the duodenal obstruction is distal to the ampulla of Vater (85%); therefore, infants present with bilious emesis. In patients with an incomplete mucosal web, delayed presentation with symptoms of postprandial emesis may occur later in life.

Infants with duodenal obstruction are generally first detected during prenatal ultrasound evaluation. Immediately after birth, a plain abdominal radiograph shows a typical double-bubble sign if it is obtained before orogastric tube decompression of swallowed gastric air (Fig. 117.7). If distal air is present, an upper GI contrast study should be considered, not only to confirm the diagnosis of duodenal stenosis or atresia but also to exclude malrotation with midgut volvulus, which would constitute a surgical emergency.

Surgical treatment is a bypass of the duodenal obstruction with a side-to-side or proximal transverse to distal longitudinal (diamond-shaped) duodenoduodenostomy. Laparoscopic duodenal anastomosis is being performed with increasing frequency. When the proximal duodenum is markedly dilated, a tapering duodenoplasty with staples or sutures should be considered to

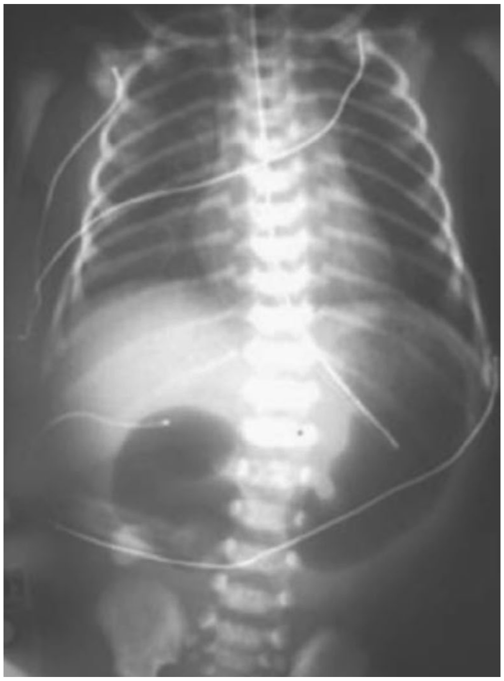

FIGURE 117.7 Plain abdominal radiograph shows double-bubble appearance of duodenal atresia.

narrow the duodenal caliber to lessen dysmotility and stasis. In patients with a duodenal mucosal web, the web is fenestrated or excised transduodenally, and caution must be exercised to avoid injury to the ampulla.

Jejunoileal atresia is the most common GI atresia, occurring in 1 in 2000 live births. It is thought to result from an intrauterine mesenteric vascular accident. Infants present with bilious emesis, abdominal distention, and failure to pass meconium. The clinical presentation varies by the location of the atretic obstruction. In proximal atresia, significant bilious emesis occurs. In distal atresias, abdominal distention with multiple dilated bowel loops is more common (Fig. 117.8A). A contrast enema study is often unnecessary to make the diagnosis of jejunoileal atresia. If obtained, it shows an extremely narrow caliber of nondistended colon. Multiple intestinal atresias can occur in 10% to 15% of cases. As a result, the distal intestine should be evaluated for atresias intraoperatively with saline injection via a soft, red rubber catheter. Jejunoileal atresia is generally not associated with other anomalies except cystic fibrosis (CF) in approximately 10% of patients.

Jejunoileal atresias are classified into five types: type I is a mucosal web, or diaphragm; type II has an atretic cord between two blind ends of bowel with an intact mesentery; type IIIa is a complete separation of the blind ends of bowel by a V-shaped mesenteric gap; and type IIIb is an apple peel or Christmas tree deformity with a large mesenteric gap (see Fig. 117.8B), in which the distal bowel receives a retrograde blood supply from the ileocolic or right colic artery. This tenuous blood supply has implications for anastomotic failures and the potential for ischemic necrosis from volvulus. Thus, many of these infants with this type of atresia are born with reduced intestinal length and may develop short gut syndrome. In type IV, there are multiple atresias, with a string of sausage appearance.

Infants are managed for neonatal bowel obstruction, with placement of an orogastric tube and IV fluid resuscitation. At operation, the main objective is to establish intestinal continuity while preserving as much intestinal length as possible. In multiple atresias, multiple anastomoses over an endoluminal stent may be necessary. If the proximal intestine is significantly dilated, prolonged dysmotility may persist; therefore, a tapering enteroplasty of the dilated segment should be considered. However, in cases of

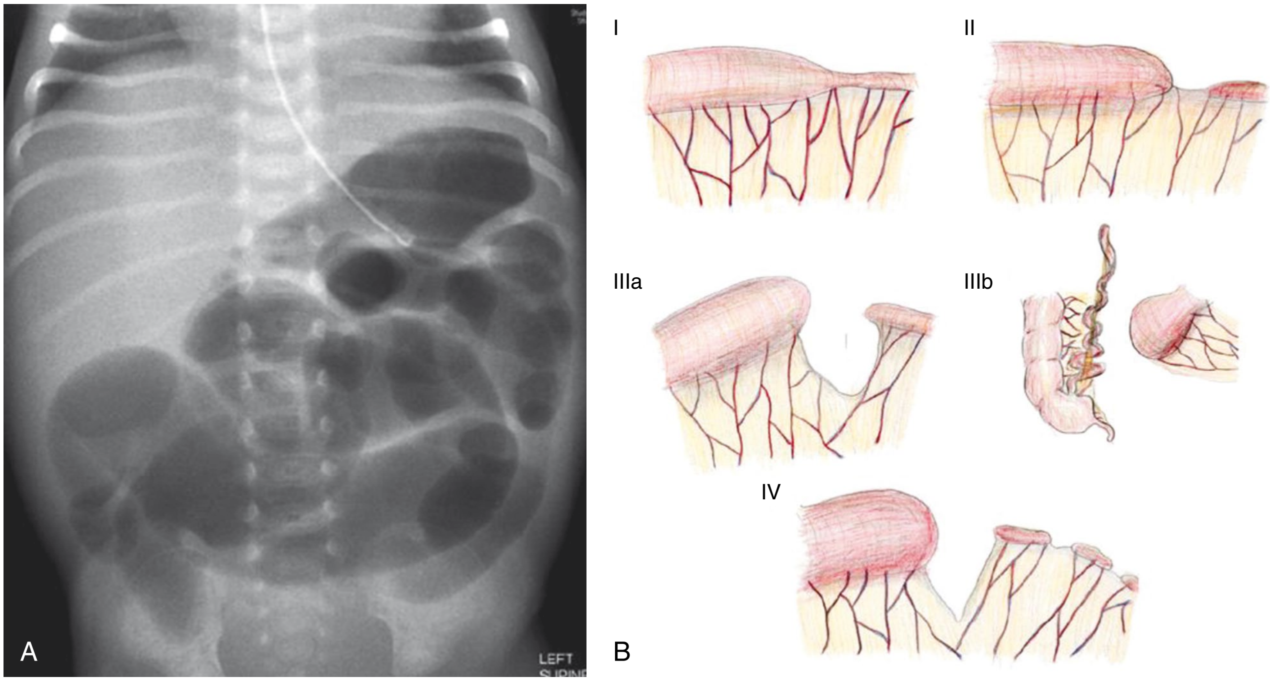

FIGURE 117.8 (A) Plain abdominal radiograph shows multiple dilated bowel loops indicating congenital bowel obstruction. (B) Jejunoileal atresias I to IV are depicted. In particular, IIIb demonstrates an apple peel type of atresia with a large mesenteric gap.

adequate bowel length, resection of the dilated segment can result in faster recovery. The overall survival for infants with jejunoileal atresia is more than 90%.

Colonic atresia is the least common, accounting for only 5% to 10% of intestinal atresia, with an incidence of 1 in 20,000 live births. Infants usually present with failure to pass meconium, abdominal distention, and bilious emesis. A plain radiograph shows multiple dilated bowel loops, but differentiation between small and large bowel is not feasible in this age group because of lack of well-developed haustra. A contrast enema study can confirm the diagnosis, but the clinical picture of distal bowel obstruction is typically sufficient to proceed with an operative exploration and diverting end colostomy versus primary colonic anastomosis.

Intestinal Malrotation and Midgut Volvulus

The actual incidence of rotational anomalies of the midgut is estimated at 2 to 5 in 1000 live births in autopsy studies. However, clinically apparent rotational anomalies are estimated to be 1 in 6000 live births. Although up to 90% of cases will be apparent before 12 months of age, as many as 1% of cases can present in adults, underscoring the importance for all surgeons to be able to diagnose and treat this disease. The actual mechanism for intestinal growth and fixation has been controversial. Historically, the midgut was thought to herniate out of the coelomic cavity through the umbilical ring at approximately the fourth week of embryonic development. By the 10th week of gestation, the intestine was thought to rotate in a counterclockwise rotation around the axis of the superior mesenteric artery (SMA) for 270 degrees. By the 12th week of gestation, the intestine returns into the abdominal cavity with the duodenum and colon becoming fixated in their normal configuration. Studies in rat embryos have demonstrated that there is no evidence of intestinal rotation. Instead, they documented two distinct embryologic processes. The first process involves rapid, localized, longitudinal growth of the duodenum, which pushes the duodenojejunal segment beneath the mesenteric root as the intestine grows outside the abdominal cavity. Once the intestinal growth is complete, the intestine returns to the abdominal cavity. The colon and rectum appear to change minimally during this process with only the cecum exiting the abdominal cavity. The cecum appears to return passively into the abdomen into the right lower quadrant. These conclusions support the different clinical manifestations of malrotation where the course of the duodenum is abnormal, whereas the position of the cecum is less indicative of the presence of malrotation. Many of the congenital anomalies that occur during the 4th to 12th weeks of gestation, such as diaphragmatic hernia, gastroschisis, or omphalocele, are associated with anomalies of intestinal rotation. Typically, these anomalies are termed nonrotation and can appear similar to cases of malrotation that have been surgically corrected with a Ladd's procedure.

Failure of the normal developmental process of intestinal growth and fixation results in the duodenojejunal and ileocecal junctions lying close together, with the midgut suspended on a narrow SMA stalk. This can twist, resulting in midgut volvulus, which can be demonstrated on an upper GI contrast series (Fig. 117.9A). The ultrasound examination may be a useful tool for the diagnosis of intestinal malrotation, in which the normal relationship of the superior mesenteric vessels (the vein is to the right of artery) is reversed or altered. Clinical presentations vary from completely asymptomatic, early satiety or weight loss, chronic intermittent crampy abdominal pain suggestive of partial obstruction, or midgut volvulus with shock and possible death. Most symptomatic patients with intestinal malrotation present at less than 1 year of age. The abdominal examination may be unremarkable. A distended abdomen is a late sign, and along with metabolic acidosis may represent the onset of life-threatening intestinal ischemia.

Midgut volvulus is a true surgical emergency because of progressive intestinal ischemia. The acute onset of bilious emesis in a particularly somnolent or lethargic newborn is an ominous sign and mandates investigation for malrotation. Midgut volvulus may also be incomplete or intermittent. With partial, intermittent volvulus, the resultant mesenteric venous and lymphatic obstruction may impair nutrient absorption and produce protein loss into the gut lumen, as well as mucosal ischemia and melena as a result of arterial insufficiency.

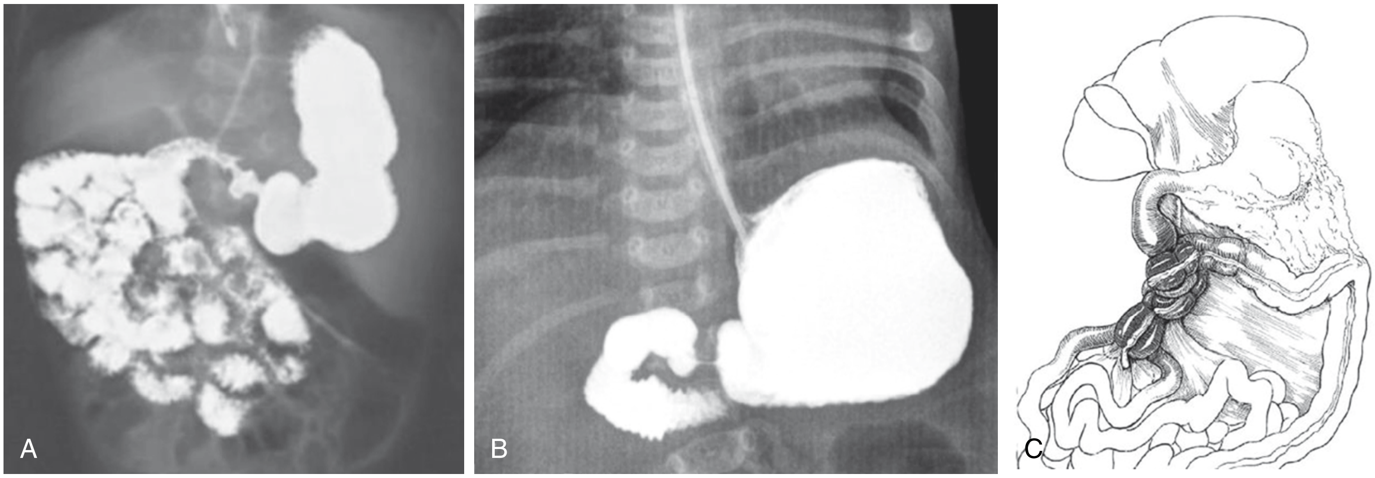

FIGURE 117.9 (A) Intestinal malrotation. Duodenal C-loop does not cross the midline, and the proximal small bowel is on the right side of the abdomen. (B) Midgut volvulus as demonstrated by a corkscrew appearance of contrast abruptly tapering off in the duodenum. (C) Diagram depicting midgut volvulus from intestinal malrotation. At operation, volvulized small bowel is untwisted in a counterclockwise fashion to restore intestinal perfusion. The peritoneal attachment between the cecum and retroperitoneum (Ladd's band) is divided as part of Ladd's procedure.

Abdominal radiographs may demonstrate upper intestinal obstruction or a gasless abdomen; however, these findings are nonspecific. The upper GI contrast study is the diagnostic study of choice in a hemodynamically stable patient. It demonstrates an obstructive upper GI pattern with the appearance of a bird's beak in the third portion of the duodenum (see Fig. 117.9B). In the acutely ill infant or child with signs and symptoms suggestive of midgut volvulus and obstruction, immediate operative exploration is warranted without an upper GI study. Aggressive resuscitation can be performed en route to the operating room as well as intraoperatively. Time is of the essence if maximal intestinal salvage is to be achieved.

Ladd's procedure was first described by William Ladd in 1936 and remains the operation of choice for rotational anomalies of the intestine. Upon entering the peritoneal cavity, chylous ascites from obstructed lymphatics may be seen. The first priority is to untwist the mesentery to reestablish blood flow to the intestine. This process can be challenging due to anatomic variability. Using the root of the mesentery and the duodenum as reference points can help to untwist the intestine quickly (see Fig. 117.9C). The intestine may be congested and edematous, and some areas may appear ischemic despite complete untwisting of the volvulus. Warm sponges placed on the bowel surface may help to improve perfusion. The decision must be made as to whether the intestine has restored adequate perfusion and is thought to be viable. If vascular integrity has been compromised, ischemic or necrotic bowel segments are resected. However, borderline ischemic segments may be left in place with a second-look laparotomy performed after 24 to 36 hours. Next, the lateral peritoneal attachments, or Ladd's bands, from the right colon to the lateral abdomen are identified and divided. As the right colon is in a more medial position than normal, these bands will tend to constrict the root of the mesentery and the duodenum, causing obstruction. This will result in the cecum becoming freely mobile in the abdomen. Next, the attachments around the anterior and posterior duodenum must be divided to straighten the duodenum, resulting the in duodenojejunal junction in the right lower quadrant of the abdomen. After this, the bands at the base of the mesentery, specifically across the superior mesenteric vein, must be divided to the level of the root of the mesentery. Upon completion of this step, the intestine will often have significantly improved perfusion and will usually have vigorous peristalsis. An appendectomy is performed, and the cecum is returned to the abdomen in the left upper quadrant with the small intestine in right side of the abdomen. This step ensures that mesentery is flat and broad with the duodenojejunal and ileocecal junctions as far apart as possible, minimizing the risk of subsequent volvulus. Securing the cecum or duodenum to the abdominal wall by sutures has no proven benefit. In addition, an intraluminal duodenal obstruction may coexist; therefore, an orogastric tube may be advanced into the distal duodenum to exclude any associated anomaly. Recurrent midgut volvulus has been reported in up to 10% of patients following the Ladd procedure. Prolonged postoperative ileus is common, particularly if a volvulus has progressed to necrosis, requiring extensive resection. Midgut volvulus accounts for approximately 18% of short bowel syndrome (SBS) in the pediatric population.

Necrotizing Enterocolitis

NEC is the most common GI surgical emergency in neonates. While multiple contributing factors have been identified—including ischemia, bacterial overgrowth, cytokines, and enteral feeding—prematurity remains the most significant risk factor. The overall incidence of NEC appears to have decreased in recent years due to clinical pathway–based gradual feeding regimens including the more prevalent use of breast milk. The exact cause of NEC remains unclear despite multiple active basic and translational studies across the world.

The clinical presentation of NEC can vary widely. Acute abdominal wall cellulitis, distention and tenderness, and feeding intolerance with gross or occult blood in the stool are hallmark features for NEC (Fig. 117.10A). Other nonspecific signs include temperature instability and episodes of apnea or bradycardia. NEC typically occurs in the first few days of life with the initiation of enteral feedings; 80% of cases occur during the first month of life. As NEC progresses, sepsis may develop with subsequent shock, hemodynamic deterioration, and coagulopathy. The pathognomonic radiographic feature of NEC is pneumatosis intestinalis (see Fig. 117.10B). Pneumatosis is composed of hydrogen gas generated by the bacterial fermentation of luminal substrates. Other radiographic findings may include portal venous gas, ascites, fixed loops of small intestine, and free air. In the majority of cases of NEC, the distal ileum and ascending colon are the areas affected. In rare cases, NEC totalis occurs where the entire GI tract is affected.

Medical management consists of orogastric tube decompression, fluid resuscitation, and broad-spectrum antibiotics. NEC can be successfully treated medically in more than 50% of cases. Infants are closely monitored for any signs of surgical indications. The absolute indication for operative intervention is the presence of free air on plain abdominal radiographs. Relative indications for surgery include clinical deterioration, persistent acidosis, abdominal wall cellulitis, palpable mass (matted ischemic bowel), a persistent fixed bowel loop on radiograph, and portal venous gas. The general surgical principles are to resect all nonviable intestinal segments, preserving maximum intestinal length with ostomy diversion, or leaving the patient in discontinuity, utilizing damage control principles. At times, multiple necrotic segments of bowel are resected, thus preserving viable intersegments. In cases of ischemic, but not frankly necrotic bowel, a second-look operation may be performed after 24 to 48 hours. Bowel resection with primary anastomosis may be considered in rare stable infants with a focal isolated perforation and minimal peritoneal contamination; however, the high risks of anastomotic leak and stricture have tempered enthusiasm for this approach. Initially, all patients were taken for exploratory laparotomy. In the 1970s, some centers reported success in treating extremely low birth weight premature infants with perforated NEC by using bedside peritoneal drainage. Peritoneal fluid and succus removal may improve abdominal distention and ventilation while halting the progression of sepsis. Over time, drain placement was found to be effective in temporizing intestinal perforation and was found to be the definitive intervention in some infants. Evidence to support peritoneal drainage as an accepted mode of treatment for NEC was established in a multicenter, randomized prospective clinical trial and has since been verified in other prospective studies.[14] In this study, survival, need for parenteral nutrition, and length of hospital stay were similar for NEC infants weighing less than 1500 g treated by peritoneal drainage or laparotomy, providing pediatric surgeons with another viable means to treat NEC in this extremely fragile patient population. Intestinal strictures may develop after medical or surgical management of NEC in approximately 10% of infants. Because of the risk for post-NEC stricture, most notably in the splenic flexure of the colon, a contrast enema study is

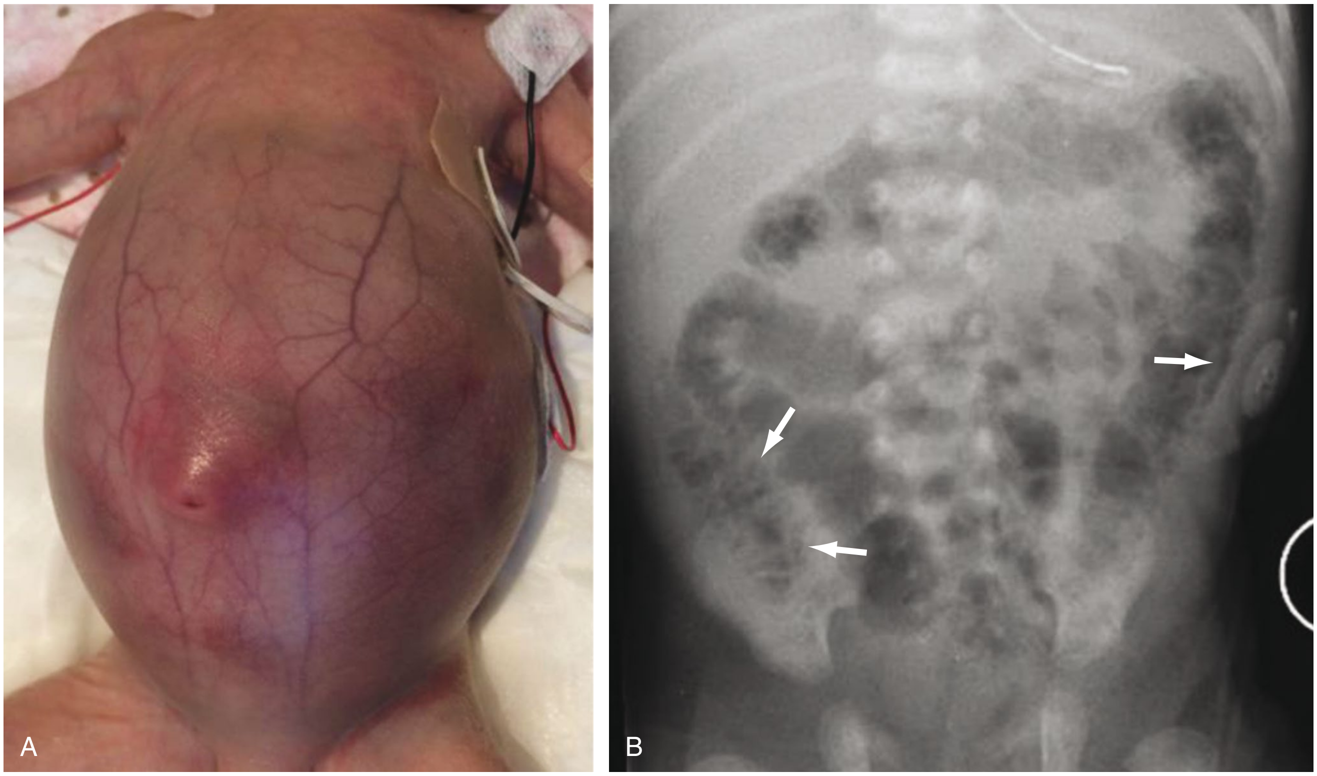

FIGURE 117.10 (A) Premature infant with necrotizing enterocolitis. Abdominal distention with marked cellulitis and dusky abdominal indicates intraabdominal catastrophe. (B) Pneumatosis intestinalis *(arrows),* a pathognomonic radiographic sign for necrotizing enterocolitis.

routinely performed before stoma reversal. NEC remains the most common cause of short gut syndrome. In addition, neurodevelopmental delay is a frequent long-term complication. Overall, the mortality rate for surgically managed NEC ranges from 10% to 50% of short gut syndrome. In addition, neurodevelopmental delay is a frequent long-term complication. Overall, the mortality rate for surgically managed NEC ranges from 10% to 50%.

Short Bowel Syndrome

SBS is a clinical condition in which the intestine is not able to absorb sufficient nutrients and/or fluids to maintain normal growth. Although this is typically the result of massive small bowel resection, SBS may occur in patients with apparently sufficient intestinal length. Common conditions that can lead to SBS are NEC (35%), intestinal atresia (25%), gastroschisis (18%), and midgut volvulus (14%). In SBS, intestinal function depends on a number of factors, such as villous architecture, total bowel length, bowel diameter, presence of the ileocecal valve, residual intestinal segments, stasis, and the presence bacterial overgrowth. In general, patients with 35 to 40 cm of length have a 50% probability of weaning from TPN with each subsequent centimeter increasing the rate of enteral autonomy by 4%. The jejunum is the site of absorption of most macronutrients and minerals. The ileum is essential for the absorption of carbohydrates, proteins, fluids, and electrolytes. In addition, bile acids, vitamin B_{12}, and the fat-soluble vitamins (A, D, E, and K) are primarily absorbed in the ileum. In the past, ileocecal valve function was thought to be important in SBS. More recent literature has demonstrated that the terminal ileum has the greatest capacity to adapt and that the presence of the ileocecal valve may serve as a surrogate for presence of a significant portion of terminal ileum. The colon is important in SBS patients for absorption of water and electrolytes. After massive small bowel resection, a physiologic process known as intestinal adaptation occurs to compensate for the loss of intestinal length. Many factors are involved in this adaptive process to enhance the absorptive function of the residual intestine, such as use of elemental diet, growth factors, and titration of TPN. Several surgical techniques (excluding small bowel transplantation) aimed at slowing intestinal transit time or increasing the mucosal surface area for enhanced absorption have been described.[15] These include reversed intestinal segment, recirculating loop, artificial intestinal valve, colon interposition, and intestinal pacing. Over time, these techniques have fallen out of favor due to poor efficacy. Currently, the two procedures that are used are the Bianchi procedure and serial transverse enteroplasty (STEP), both of which focus on increasing intestinal length while reducing intestinal caliber.

The Bianchi procedure[16] was originally described an intestinal lengthening procedure in which the mesenteric vascular bed is separated into two systems, the dilated small intestine is split into two parallel segments, each with its own mesenteric blood supply, and the ends are approximated (Fig. 117.11A). This resulted in a 50% decreased diameter of the small intestine and increased length by 100%. The Bianchi procedure has been shown to be an effective surgical option for treating patients with SBS, but has not been used widely because it is technically demanding and risks losing intestinal length if the blood supply is damaged during dissection.

In contrast to the Bianchi procedure, STEP uses the principle of minimal bowel dissection by serially stapling dilated small intestine in a transverse fashion to create a narrower lumen resulting

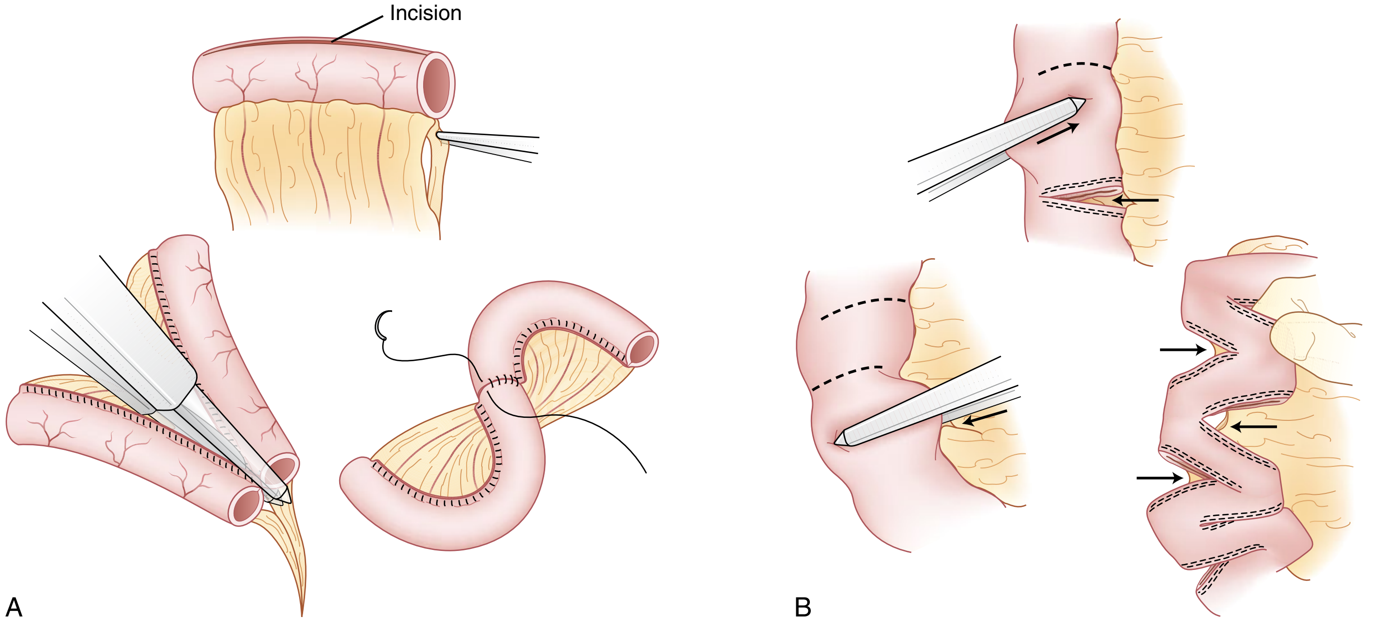

FIGURE 117.11 Bowel-lengthening procedures. (A) Bianchi technique separates two mesenteric planes. A dilated segment of bowel is stapled longitudinally to create two narrower segments for sequential anastomosis. (B) Serial transverse enteroplasty involves stapling a dilated bowel into V shapes on alternating sides, decreasing width and increasing length. (A, Adapted from Abu-Elmagd KM, Bond G, Costa G, et al. Gut rehabilitation and intestinal transplantation. *Therapy*. 2005;2:853-864. B, From Kim HB, Fauza D, Garza J, et al. Serial transverse enteroplasty [STEP]: a novel bowel-lengthening procedure. *J Pediatr Surg*. 2003;38:425-429.)

in longer intestinal length (see Fig. 117.11B).[17] The STEP procedure has been shown to improve enteral feeding tolerance, resulting in significant catch-up growth, without increased mortality. In addition, the operation is technically easier and may be repeated if the bowel continues to dilate as the patient grows. An improved enteral tolerance in the majority of 20 treated patients was observed for more than a 7-year period after STEP procedures.[18] A recent retrospective, single institution review of 36 patients reported that the median increase in bowel length after STEP was 53% and that 42% reached enteral autonomy, but it emphasized the importance of a multidisciplinary intestinal rehabilitation program for an ideal patient selection and outcomes.[19]

Meconium Ileus

Meconium ileus is a unique form of neonatal obstruction that occurs in infants with CF, an autosomal recessive disorder resulting from a mutation in the CF transmembrane regulator gene *(CFTR)*. It is estimated that 3.3% of the White population in the United States are asymptomatic carriers of the mutated *CFTR* gene. The abnormal chloride transport in patients with CF results in tenacious viscous secretions with a protein concentration of almost 80% to 90%. It affects a wide variety of organs, including the intestine, pancreas, lungs, salivary glands, reproductive organs, and biliary tract.

Meconium ileus in the newborn represents the earliest clinical manifestation of CF, affecting approximately 10% to 15% of patients with this inherited disease. The incidence of CF ranges from 1 in 1000 to 2000 live births. Infants present with three cardinal signs in the first 24 to 48 hours of life: (1) generalized abdominal distention, (2) bilious emesis, and (3) failure to pass meconium. Maternal polyhydramnios occurs in approximately 20% of cases. In simple meconium ileus, the terminal ileum is dilated and filled with thick, tarlike, inspissated meconium. Smaller pellets of meconium are found in the more distal ileum, leading into a relatively small colon. In patients with simple meconium ileus, important plain abdominal radiographic findings include dilated and gas-filled loops of small bowel, absence of air-fluid levels, and a mass of meconium in the right side of the abdomen mixed with gas, giving a ground-glass or soap bubble appearance. Abdominal radiographs show dilated bowel loops with relatively absent air-fluid levels because of thick, viscous meconium. A contrast enema using the water-soluble ionic solution Gastrografin can be both diagnostic-demonstrating a small, narrow-caliber colon and inspissated meconium pellets in the terminal ileum-and therapeutic, as it aids in the evacuation of meconium by pulling water into the colon. It is imperative for an infant to be well hydrated and monitored closely. It is successful in relieving the obstruction in up to 75% of cases, with a bowel perforation rate of less than 3%. The pilocarpine iontophoresis sweat test revealing a chloride concentration of more than 60 mEq/L is the most definitive method to confirm the diagnosis of CF. A more immediate test is detection of the mutated *CFTR* gene.

Operative management of *simple* meconium ileus is required when the obstruction is persistent despite contrast enema, along with 5 mL of 10% *N*-acetylcysteine (Mucomyst) solution administered every 6 hours through a nasogastric tube. Historically, the dilated terminal ileum was resected and various types of stomas were created, allowing intestinal decompression and recovery. However, enterotomy, irrigation with warmed saline solution or 4% *N*-acetylcysteine, and simple evacuation of the luminal meconium without a stoma has also been advocated. *N*-acetylcysteine serves to break the disulfide bonds in the meconium to facilitate separation from the bowel mucosa. The meconium is manipulated into the distal colon or removed through the enterotomy. After the obstruction is relieved, the enterotomy is closed in standard fashion. If meconium evacuation is incomplete, a T-tube may be left in place in the ileum or a divided stoma may be created to facilitate continued postoperative irrigation.

Meconium ileus is considered *complicated* when perforation of the intestine has taken place in utero or in the early neonatal period. Extravasation of meconium can result in severe peritonitis, with a dense inflammatory response and calcification. The variable clinical presentations include a meconium pseudocyst, adhesive peritonitis with or without secondary bacterial infection, and ascites. Abdominal radiographs can demonstrate calcifications, bowel dilation, mass effect, and ascites. A distal ileal obstructive syndrome (DIOS), formerly known as meconium ileus equivalent, may develop in older patients as a consequence of noncompliance with oral enzyme replacement therapy or bouts of dehydration. This is managed nonoperatively in most patients with enemas or oral polyethylene glycol solutions. Other diagnoses must also be considered, including simple adhesive intestinal obstruction. Patients with CF who develop or are at risk for exocrine pancreatic insufficiency are treated with enteric-coated, high-strength pancreatic enzyme replacement therapy (PERT). A complication of this therapy may be a fibrosing colonopathy, which requires exploration and resection of the inflammatory colon stricture.

Meconium Plug Syndrome

Meconium plug syndrome is a different condition from meconium ileus, and, in most cases, it is not a sequela of CF. However, it is a frequent cause of neonatal intestinal obstruction and is associated with several conditions, including Hirschsprung disease, maternal diabetes, and hypothyroidism. Infants often present with abdominal distention and failure to pass meconium in the first 24 hours. The contrast enema study shows a microcolon full of thickened meconium plugs that extends up to where the proximal colon is dilated. Often, a contrast enema is both diagnostic and therapeutic and surgical intervention is not indicated.

Hirschsprung Disease

The pathogenesis of Hirschsprung disease is an aganglionated distal colon/rectum, characterized by an absence of ganglion cells in the myenteric (Auerbach) and submucosal (Meissner) plexus. It occurs in 1 in 5000 live births, with male infants being affected four times more frequently than female infants. Of these patients, 3% to 5% have Down syndrome, and the risk for Hirschsprung disease is greater if there is a family history. An abnormal locus on chromosome 10 has been identified in some families and is associated with the *RET* oncogene.[20] This neurogenic, parasympathetic abnormality is associated with failure of propagation of peristaltic waves with absent muscular relaxation of the distal colon and internal anal sphincter, resulting in a functional obstruction. Hence, the abnormal bowel is the externally normal caliber distal segment, whereas the normal bowel is the proximal dilated portion. Aganglionosis begins at the anorectal line, with the transition to normal colon occurring in the rectosigmoid colon in approximately 80% of cases, in the splenic or transverse colon in 17%, and in the small intestine (involving the entire colon) in 8%. The area between the dilated and contracted segments is referred to as the transition zone. Here, ganglion cells begin to appear, but in reduced numbers.

Most infants (>90%) present with abdominal distention and bilious emesis with failure to pass meconium within the first 24 hours of life. Those with missed diagnoses of Hirschsprung disease may present later in life with a chronic history of abdominal distention and constipation. Enterocolitis is the leading cause of death in patients with uncorrected Hirschsprung disease. It may present with alternating episodes of diarrhea and obstipation, along with abdominal distention, fever, hematochezia, peritonitis, shock, and potentially death.

The diagnostic imaging study of choice in a newborn is a contrast enema. In Hirschsprung disease, aganglionosis of the distal rectum usually results in a narrow caliber with a transition zone and dilated, normal, proximal sigmoid colon. Failure to evacuate the instilled contrast medium completely after 24 hours strongly indicates the presence of Hirschsprung disease. Contrast enema studies are useful in excluding other causes of constipation, such as meconium plug, small left colon syndrome, and intestinal atresia. In toddlers, a manometry study revealing failure of the internal sphincter to relax upon rectal balloon distention may be diagnostic. A rectal biopsy proximal to the dentate line is the gold standard for the diagnosis of Hirschsprung disease. In the newborn period, this is performed at bedside using a suction rectal biopsy kit. It is imperative to obtain biopsy specimens at least 5 mm to 1 cm above the dentate line to avoid sampling the anoderm. In infants, two or more suction rectal biopsy specimens, 1 cm apart in the posterior rectum, are recommended. In older children, a full-thickness biopsy specimen is obtained under general anesthesia because the thicker rectal mucosa is not amenable to the suction biopsy technique. Absent ganglia, hypertrophied nerve trunks, and robust immunostaining for acetylcholinesterase are the histopathologic criteria. Calretinin immunostaining has become a standard adjunct histology study for the diagnosis of Hirschsprung disease.[21] Once the diagnosis is confirmed, the disease can be managed by daily rectal irrigations using a soft red rubber catheter and warm NS. Irrigations are typically performed one to times per day using as much saline as is necessary to return a clear effluent. Irrigations may not be effective or even possible in patients with other comorbidities, when family circumstances hinder proper use of irrigations, or when long segment disease is present. In these cases, leveling colostomy with intraoperative biopsies to determine the site of normal ganglionated intestine may be necessary.

The definitive surgical procedure for Hirschsprung's disease was originally described by Orvar Swenson in 1949. The Swenson pull-through procedure involves a full-thickness dissection of the rectum, freeing it from the surrounding sphincter mechanism. This dissection can be started in the abdomen and extended distally or start 5 mm to 1 cm proximal to the dentate line and extend proximally. It has also been described using laparoscopic assistance or a completely transanal approach. The dissection is carried out to the level of the normal, ganglionated intestine with verification using intraoperative frozen biopsies. Finally, the coloanal anastomosis is performed. The most commonly used surgical procedure for Hirschsprung disease is the laparoscopic-assisted Soave pull-through procedure.[22] (Of note, this procedure is traditionally called the Soave procedure. However, Dr. Asa Yancey described this operation and published it 2 years earlier.) Once frozen section evaluation is completed, an endorectal mucosal dissection within the aganglionic distal rectum is performed via a transanal approach, 5 mm proximal to the dentate line. Once the dissection is at the level of the intraabdominal rectum, the dissection plane is converted to the full thickness of the colon. The ganglionated normal colon is then pulled through the remnant muscular cuff after posterior myotomy of the cuff is performed. Then, a coloanal anastomosis is performed. The Soave procedure can also be performed entirely through a transanal approach. The third pull-through procedure that is commonly used is the Duhamel procedure. In this procedure, the level of disease is confirmed as described earlier using intraoperative frozen biopsies.

Next, the anterior wall of the aganglionic rectal cuff is left in place and the ganglionated normal colon is pulled posterior to the cuff. The aganglionic cuff is anastomosed to the normal ganglionated colon in a side-to-side fashion, creating a common reservoir. This anastomosis results in the formation of a neorectum that empties normally because of the posterior segment of ganglionated bowel. The functional results of these three techniques are similar when performed in skilled hands. Although management with rectal irrigations and one-stage pull-through has become the standard approach for the majority of patients with Hirschsprung disease, two- or three-stage operations involving initial leveling colostomy followed by a definitive pull-through may be necessary in certain cases.

Postoperatively, the stool dysfunction can persist, and at times, it can be difficult to manage, requiring intermittent rectal decompression. Constipation is a common postoperative problem along with frequent soiling, incontinence, and postoperative enterocolitis. A close follow-up of patients postoperatively is mandatory along with aggressive control of constipation with stool softeners and laxatives. If symptoms persist, a histologic reevaluation should be performed to confirm that a normal ganglionated segment of colon was pulled through and to rule out the presence of a transition zone at the coloanal anastomosis.

Anorectal Malformation

The incidence of imperforate anus is 1 in 5000 live births with a male predominance of 58%. The spectrum of anorectal malformations ranges from a perineal mucosal groove with normally positioned anal opening to the cloaca or single opening for the urinary, reproductive, and digestive tracts. The most common defect is an imperforate anus with a fistula between the distal colon and bulbar urethra, in males, or the vestibule of the introitus, in females. By the sixth week of gestation, the urorectal septum moves caudally to divide the cloaca into the anterior urogenital sinus and posterior anorectal canal. Failure of this septum to form results in a fistula between the bowel and urinary tract (in males) or introitus (in females). Complete or partial failure of the anal membrane to resorb results in an anal membrane or stenosis. The perineum also contributes to the development of the external anal opening and genitalia by the formation of cloacal folds, which extend from the anterior genital tubercle to the anus. The perineal body is formed by fusion of the cloacal folds between the anal and urogenital membranes. Breakdown of the cloacal membrane anywhere along its course results in the external anal opening being anterior to the external sphincter (i.e., imperforate anus with perineal fistula).

An anatomic classification of anorectal anomalies is based on the fistula present in the rectum. Male infants can have rectoperineal (Fig. 117.12), rectobulbar urethra, rectoprostatic urethra, or recto-bladder neck fistulas or no fistula. Female infants can have rectoperineal or rectovestibular fistulas, no fistula, or a cloacal anomaly. In the past, these defects were classified as low, intermediate, or high in relationship to the levator ani musculature. This classification is used less in favor of anatomic description of the fistula site. A more therapeutic and prognostic classification is depicted in Box 117.1. An invertogram, a lateral pelvic radiograph taken after the infant is held upside down for several minutes, was used in the past to determine the most distal point of the rectal pouch in patients (typically males) with no visible fistula. Currently, divided loop colostomy with distal colostogram is used to delineate the location of the fistula. Rectal atresia, commonly associated with trisomy 21, refers to an unusual lesion in which the lumen of the rectum is completely or partially interrupted, with the upper rectum dilated and the lower rectum consisting of a small anal canal. A cloaca is defined as a defect in which the rectum, vagina, and urethra all fuse to form a single common channel. The severity of this lesion is characterized by the length of the common channel, with 3 cm being the cutoff between short and long defects. In females, a single orifice in the perineum indicates a cloaca. If two perineal orifices are seen in a female, a urogenital sinus with normally positioned anus or a urethra and vagina with no rectal fistula are the most likely scenarios. Anorectal malformations often coexist with other lesions, and the VACTERL association must be considered during evaluation. Bone abnormalities of the sacrum and spine, such as absent vertebrae, accessory vertebrae, and hemivertebrae or an asymmetrical or short sacrum, can occur in approximately one-third of patients. Absence of two or more vertebrae is associated with a poor prognosis for bowel and bladder continence. Occult dysraphism of the spinal cord may also be present, consisting of a tethered cord, lipomeningocele, or fat within the filum terminale and warrant imaging to assess.

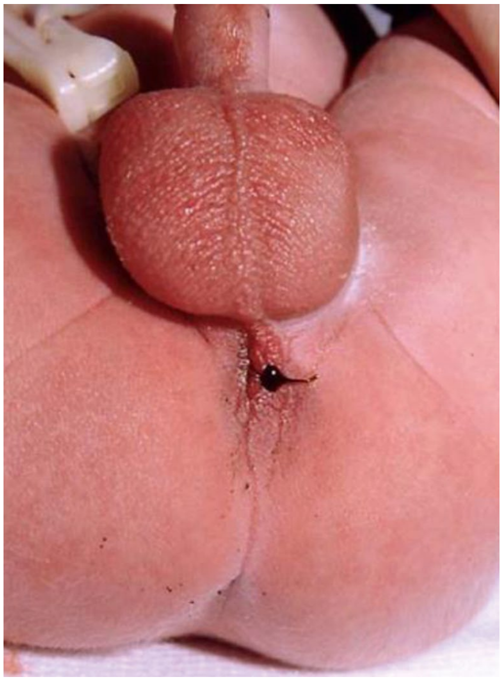

FIGURE 117.12 Imperforate anus with perineal fistula opening demonstrating meconium. Gluteal and scrotal anatomy appear relatively normal, consistent with characteristic findings in blind rectal pouch close to perineal skin amenable to anorectoplasty without an ostomy.

BOX 117.1 Classification of Congenital Anomalies of the Anorectum

Female	Male
Cutaneous (perineal fistula)	Cutaneous (perineal fistula)
Vestibular fistula	Rectourethral fistula
Imperforate anus without fistula	Bulbar
Rectal atresia	Prostatic
Cloaca	Recto-bladder neck fistula
Complex malformation	Imperforate anus without fistula
	Rectal atresia

Genitourinary abnormalities other than rectourinary fistula occur in 25% to 60% of patients. Vesicoureteral reflux and hydronephrosis are the most common, but other conditions—such as horseshoe, dysplastic, or absent kidney, as well as hypospadias or cryptorchidism—must be considered. In general, the higher the anorectal malformation, the greater the frequency of associated urologic abnormalities. In patients with a persistent cloaca or rectovesical fistula, the likelihood of a genitourinary abnormality is approximately 90%. In contrast, the frequency is only 10% with low defects (e.g., perineal fistula). Renal ultrasound and voiding cystourethrography are obtained to assess the urinary tract. If a cardiac defect is suspected, echocardiography is performed before any surgical procedure. EA must also be ruled out with an orogastric tube placement. The decision algorithms for the management of male and female newborns with anorectal malformation are shown in Figs. 117.13 and 117.14.

A newborn with a perineal or vestibular fistula may undergo a primary single-stage repair without colostomy. For anal stenosis in which the anal opening is in a normal location, serial dilation alone is usually sufficient. Dilations are performed daily with gradual size increase over time. If the anal opening is anterior to the external sphincter (i.e., rectoperineal fistula), with a small distance between the opening and the center of the external sphincter, and the perineal body is intact, a cutback anoplasty or limited posterior sagittal anorectoplasty (PSARP) is indicated to operatively restore the anal opening to the normal position within the center of the sphincter muscles, with reconstruction of the perineal body. Newborns suspected of having a rectourinary tract fistula or with blind rectal pouch generally require an initial loop colostomy as the first part of a three-stage reconstruction. The colon is completely divided, and an end sigmoid colostomy with a mucous fistula is constructed to minimize fecal contamination in the rectourinary fistula. Furthermore, the distal mucous fistula limb can be used later for a contrast study to determine the rectourinary fistula. The second-stage procedure is usually performed at 3 to 6 months of age. PSARP, as first described by deVries and Peña, is the procedure of choice.[23] This consists of determining the location of the central position of the anal sphincter by electrical stimulation of the perineal musculature throughout the operation. An incision is then made in the midline buttocks, extending from the coccyx to the anterior perineum, through the sphincter and levator musculature, until the rectum is identified. The fistula from the rectum to the urinary tract is divided. The rectum is mobilized and the perineal musculature reconstructed. The third and final stage is colostomy reversal, which is performed several weeks later. Anal dilations begin 2 weeks after the anorectoplasty and continue for several months after the colostomy closure.

A laparoscopic-assisted pull-through anorectoplasty has been described for anorectal malformations with similar short-term outcomes to PSARP. This technique offers the theoretical advantages of placing the neorectum within the central position of the sphincter and levator muscle complex under direct vision and avoids the need to cut across these structures. The long-term outcome of this new approach compared with the standard PSARP is unknown.

Complications of anorectal malformations relate to their associated anomalies. Social fecal continence is the major goal regarding correction of the defect. Prognostic factors for continence include the level of the pouch and whether the sacrum is normal. In general, 75% of patients have voluntary bowel movements. However, 50% of patients in this group continue to experience occasional fecal soiling, while the remaining 50% are considered fully continent. Constipation is the most common sequela. A bowel management program consisting of a combination of oral stool softeners and laxatives along with close outpatient follow-up is vital to reduce the frequency of soilage and to improve the quality of life for these patients.

Intussusception

Ileocolic intussusception is a telescoping of distal ileum into the cecum. It is usually idiopathic, without an obvious anatomic lead point, and occurs predominantly at the ileocecal junction, where

there is marked swelling of the lymphoid tissue in the region of the ileocecal valve. It is unknown whether this represents the cause or effect of the ileocolic intussusception. The occurrence of intussusception is associated with a history of recent episodes of viral gastroenteritis, upper respiratory infections, and even administration of the rotavirus vaccine, implicating lymphoid swelling in the pathogenesis of intussusception. In older children, the incidence of a pathologic lead point is up to 12%, and Meckel's diverticulum is found to be the most common lead point for intussusception. However, other causes, such as intestinal polyps, an inflamed appendix, submucosal hemorrhage associated with Henoch-Schönlein purpura, a foreign body, ectopic pancreatic or gastric tissue, and intestinal duplication, must also be considered. Postoperative small bowel–small bowel intussusception without a lead point can occur in up to 5% of pediatric intussusception cases, typically following retroperitoneal surgery.

Intussusception produces severe, intermittent cramping abdominal pain in an otherwise healthy child from 3 months to 3 years. Half of children presenting with intussusception are younger than 1 year of age and less than 25% occur after age 2. The child often draws their legs up during the pain episodes and is usually quiet during the intervening periods. Other symptoms include vomiting, passage of bloody mucus (currant jelly stool), and a palpable abdominal mass. In approximately 50% of cases, the diagnosis of ileocolic intussusception can be suspected on plain abdominal radiographs by the presence of a mass, sparse colonic gas, or complete distal small bowel obstruction. Currently, abdominal ultrasound is used as an initial diagnostic test. The characteristic sonographic findings—such as the 'target sign' on a transverse view and the 'pseudokidney sign' seen longitudinally—should prompt an air-contrast enema study.

Hydrostatic reduction by enema using contrast material or air is the therapeutic procedure of choice. Contraindications to this approach include the presence of peritonitis and hemodynamic instability. Furthermore, an intussusception located entirely within the small intestine is unlikely to be reduced by an enema and is more likely to have an associated pathologic lead point and require surgery. Successful reduction is accomplished in more than 80% of cases, confirmed by resolution of the mass, along with reflux of air or contrast into the terminal ileum, and many of these patients can be discharged without hospital admissions. For those presentations that are refractory to initial air enema attempt, many centers try a repeat air enema study a few hours later with some success.[24] The recurrence rate after hydrostatic reduction is ~11% and usually occurs within 24 hours after the reduction. When it recurs, it is usually managed by another air enema reduction. A third recurrence may be an indication for operative management. High fevers are common after reduction of the intussusception and typically resolve without sequelae.

The operative indications for intussusception include peritonitis, bowel obstruction at initial presentation, failed hydrostatic enema reduction, or multiple recurrences. This procedure can be approached in an open or laparoscopic fashion. The intussusceptum is reduced in a retrograde fashion by pushing the mass proximally. Once it is reduced, viability of the reduced bowel is examined. The lymphoid tissue in the ileocecal region is thickened and edematous and may be mistaken for a tumor within the small bowel; great caution should be exercised before surgical resection. Recurrence rates are extremely low after surgical reduction. Bowel resection is required occasionally when the intussusception cannot be reduced, the viability of the bowel is uncertain, or a lead point is identified. If so, an ileocolectomy with primary anastomosis is usually performed.

Meckel's Diverticulum

Meckel's diverticulum is the most common congenital anomaly of the GI tract and occurs in approximately 2% of the population. More than 70% of symptomatic patients have heterotopic gastric mucosa and another 5% have pancreatic tissue. The rule of twos is often cited in association with Meckel's diverticulum. Aside from its 2% incidence and two types of heterotopic mucosa, it is located within 2 feet of the ileocecal valve, is approximately 2 inches in length, and usually symptomatic by 2 years of age. Meckel's diverticulum is caused by a failure of normal regression of the omphalomesenteric (vitelline) duct that occurs during weeks 5 to 7 of gestation. Meckel's diverticulum is a true diverticulum containing all intestinal layers and is a common manifestation of an omphalomesenteric (vitelline) remnant.

The clinical symptoms are related to hemorrhage, obstruction, or inflammation. The most common presenting symptom is a painless, massive, lower GI bleeding in children younger than 5 years. Diagnosis of a persistent vitelline duct remnant may be established by umbilical ultrasound or lateral contrast radiography. Bleeding from a Meckel's diverticulum may be confirmed by a ^{99m}Tc-pertechnetate isotope scan, which detects gastric mucosa within the diverticulum but will not detect pancreatic mucosa. Of note, ectopic gastric mucosa can also be present in patients with intestinal duplication.

Segmental ileal resection at the base of the Meckel's diverticulum, especially in the case of bleeding, with primary end-to-end anastomosis is the gold standard because the bleeding point is typically on the mesenteric side of the intestine, opposite the opening of the diverticulum. However, a simpler V-shaped diverticulectomy with transverse closure of the ileum is an acceptable alternative technique in patients who are not actively bleeding. Laparoscopic diverticulectomy has become more acceptable with several reporting no increase in complications due to retained ectopic gastric mucosa.[25] Although management of incidentally found Meckel's diverticulum at the time of laparotomy for unrelated other GI conditions has been somewhat controversial, an asymptomatic Meckel's diverticulum should be left alone.

Appendicitis

The management of appendicitis has evolved over time. Currently, the diagnosis of appendicitis is rarely made solely based on history and physical examination findings alone. Virtually every patient suspected of appendicitis undergoes extensive diagnostic blood tests and imaging studies (e.g., ultrasonography or CT). The use of MRI has also been introduced at some institutions to reduce exposure to radiation. Most institutions have adopted a clinical pathway–based management of appendicitis with standardized IV antibiotic regimens, operative techniques, and postoperative care, which include minimal to no outpatient opioid use. Laparoscopic appendectomy has become the standard approach. For simple appendicitis, preoperative IV antibiotics are administered (monotherapy with piperacillin-tazobactam is preferred), and the appendectomy can be safely performed within 24 hours without increased risk of perforation. For complicated appendicitis, surgical management includes appendectomy with antibiotics continued after surgery or percutaneous drainage or abscess with or without delayed interval appendectomy. Up to 40% of patients with perforated appendicitis can develop a postoperative abscess, which may require percutaneous drainage and/or continued antibiotics. Recently, nonoperative management of appendicitis has become more accepted in clinical practice, challenging the old dogma of appendectomy for every appendicitis. A multi-institutional trial has determined that the nonoperative management of carefully selected patients with uncomplicated appendicitis has acceptable outcomes.[26]

Further studies will be necessary to determine the long-term efficacy of this approach. However, during the recent COVID-19 pandemic, the nonoperative management of appendicitis was useful in patients with significant risk of respiratory complications due to their concurrent SARS-CoV-2 infection.

HEPATOPANCREATICOBILIARY CONDITIONS

Extrahepatic Biliary Atresia

BA is a rare disease of neonates characterized by the inflammatory obliteration of intrahepatic and extrahepatic bile ducts. The incidence is estimated to be 1 in 5000 to 12,000 infants, depending on the region. It may be associated with other congenital malformations, such as splenic abnormalities (e.g., asplenia, polysplenia), absence of the inferior vena cava (IVC), and intestinal malrotation. The exact mechanisms of BA are unknown, and the disease is progressive. One theory is that extrahepatic ducts are susceptible to immune-mediated inflammatory injury and subsequent obliteration of the bile ducts. Proinflammatory cytokines (i.e., interleukin-2, interferon-γ, and tumor necrosis factor) are implicated.[27] T cells and natural killer cells are also prominently found in BA. Another theory is that a viral insult, such as group C rotavirus infection, triggers immune-mediated fibrosclerosis and obstruction of the extrahepatic bile ducts. Interestingly, animal studies have shown that infection of newborn mice with rotavirus leads to a presentation similar to infants, with the onset of hyperbilirubinemia, jaundice, and acholic stools. Histology shows inflammation and obstruction of the extrahepatic bile ducts. Another hypothesis is that there may be an association with human leukocyte antigen (HLA) type and BA because patients with BA have a high frequency of HLA-B12. It is unclear whether this is causal, but some argue that abnormal expression of HLA makes biliary ductal epithelial cells susceptible targets for immunologic assault. Another putative gene, *CFC1,* encodes a protein important in the embryonic differentiation of the left-right axis; when mutated, it is thought to predispose to the development of BA. Histopathology shows significant extrahepatic biliary obstruction with portal tract fibrosis, inflammatory cell infiltration, bile duct proliferation, and cholestasis with bile plugging.

The disease is classified according to the level of the most proximal biliary obstruction. Type I BA has patency to the level of the common bile duct (CBD); type II has patency to the level of the common hepatic duct; and type III, which accounts for more than 90% of cases, occurs when the left and right hepatic ducts, at the level of the porta hepatis, are involved. This aids in the differentiation between correctable BA and others. Correctable BA requires that patent hepatic ducts exist to the porta hepatis. Types I and II may be amenable to a direct extrahepatic biliary duct–intestinal anastomosis.

Infants present shortly after birth with jaundice, pale stools, and dark urine. Advanced disease presents with failure to thrive, hepatomegaly, and ascites from liver cirrhosis. If the jaundice persists after 14 days of life in a term infant, an evaluation for liver disease should be initiated. This consists of determining direct or conjugated bilirubin levels, which will be elevated (>2.0 mg/dL) in those with liver disease. Other exclusionary studies include serologic testing for toxoplasmosis, rubella, cytomegalovirus, and herpes (TORCH) and hepatitis B and C infections; α_1-antitrypsin; and

CF. Metabolic disorders, such as galactosemia and tyrosinemia, and endocrine abnormalities must also be ruled out.

The gallbladder may be atrophic or absent, and intrahepatic ducts may also be notably absent on ultrasound evaluation. Hepatobiliary iminodiacetic acid (HIDA) scintigraphy, magnetic resonance cholangiopancreatography (MRCP), and endoscopic retrograde cholangiopancreatography (ERCP) are used with varying success. A HIDA scan can reveal uptake of the technetium isotope with an absence of emptying into the duodenum. MRCP or ERCP can better define the biliary anatomy, but it is more invasive and can delay operative exploration. Timing of Kasai portoenterostomy has been shown to affect postoperative outcome. Liver biopsy helps support the diagnosis of BA and can safely be done percutaneously or open. Optimal timing of operation is typically before 60 days of life, where 2-year survival with native liver is approximately 60%. If operative intervention is performed after 90 days of life, this number drops to approximately 40%.

Once the diagnosis is suspected, operative exploration with intraoperative cholangiography is indicated. The absence of contrast drainage into the duodenum confirms the diagnosis. If BA is confirmed, a hepatoportoenterostomy (Kasai procedure) is the surgical procedure of choice. Here, the extrahepatic biliary tree is dissected proximally to the level of the liver capsule, where the porta hepatis (portal plate) is transected. The dissection of the fibrous remnant ascends into the posterior area surrounding the portal vein branches until it has come within the capsular surface of the liver (Fig. 117.15A). The reconstruction is performed using a Roux-en-Y hepaticojejunostomy (see Fig. 117.15B). The use of ursodeoxycholic acid and phenobarbital may promote biliary drainage, but their efficacy is uncertain. In the past, the use of steroids after the Kasai procedure was advocated by many and thought to promote biliary drainage with shorter hospital stay. However, the Biliary Atresia Clinical Research Consortium's recent randomized, double-blinded, placebo-controlled trial of steroid therapy (the START trial) after the Kasai procedure demonstrated that high-dose steroid therapy after the procedure did not result in significant treatment differences in bile drainage at 6 months.[28] Furthermore, steroid treatment was associated with earlier onset of serious adverse events as well as with impaired growth. However, steroid pulse therapy remains a treatment option for post-Kasai cholangitis. Antibiotics are also continued postoperatively because the risk of cholangitis is high (45%–60%) due to the ease with which intestinal bacteria can ascend and colonize the bile ducts. Unfortunately, if the Kasai procedure is unable to reestablish bile flow and liver failure or cirrhosis ensues, liver transplantation is indicated.

Unfortunately, Kasai hepatoportoenterostomy does not cure BA, which will inevitably progress in more than 70% of infants who undergo this procedure. The rate with which the disease progresses, as evidenced by cirrhosis and portal hypertension, is variable, but it may be expedited by recurrent cholangitis. It is estimated, however, that 80% of those who have successfully undergone a Kasai procedure can live up to 10 years before liver transplantation is needed. In those infants who undergo transplantation, outcomes are good, with 10-year graft survival and overall patient survival of 73% and 86%, respectively.[29]

Choledochal Cyst

Choledochal cysts are cystic dilations of the CBD. They have an incidence of 1 in 100,000 to 150,000 live births, with a 3 to 4:1 female-to-male preponderance. They are classified on the basis of location, and their frequency varies (Fig. 117.16). Type I (50%–80%) is a simple cyst that can involve any portion of the CBD and can be cystic (type Ic) or fusiform (type If), whereas type II (2%) describes a diverticulum arising off any portion of

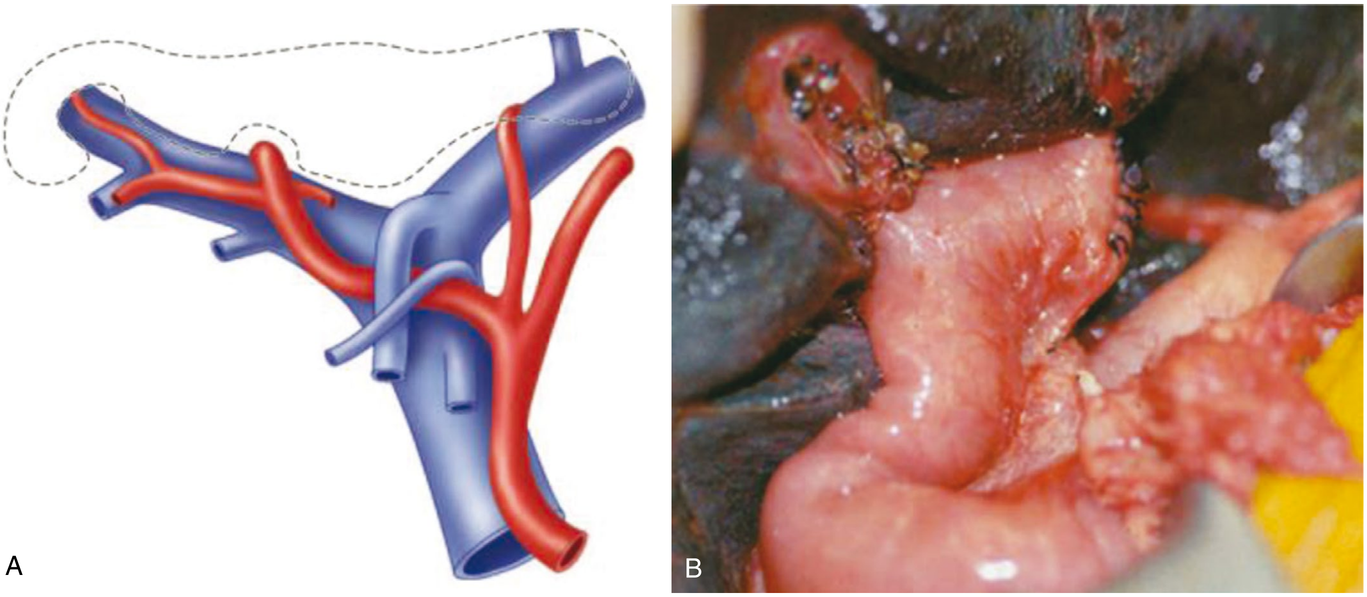

FIGURE 117.15 Liver and Kasai portoenterostomy. (A) The dissection of fibrous extrahepatic biliary remnant is continued up to the capsular surface of the liver within the bifurcation of the portal vein (*dotted line* indicates fibrous portal plate). The lateral extent of dissection on the left side is the umbilical fissure and the obliterated umbilical vein insertion into the left portal vein. On the right side, the lateral extent of dissection is to the bifurcation of the right portal vein into its anterior and posterior branches. (B) Completed Roux-en-Y portoenterostomy. (From Nathan JD, Ryckman FC. Biliary atresia. In: Chung DH, Chen MK, eds. *Atlas of Pediatric Surgical Techniques*. Philadelphia: Elsevier Saunders; 2010:220-231.)

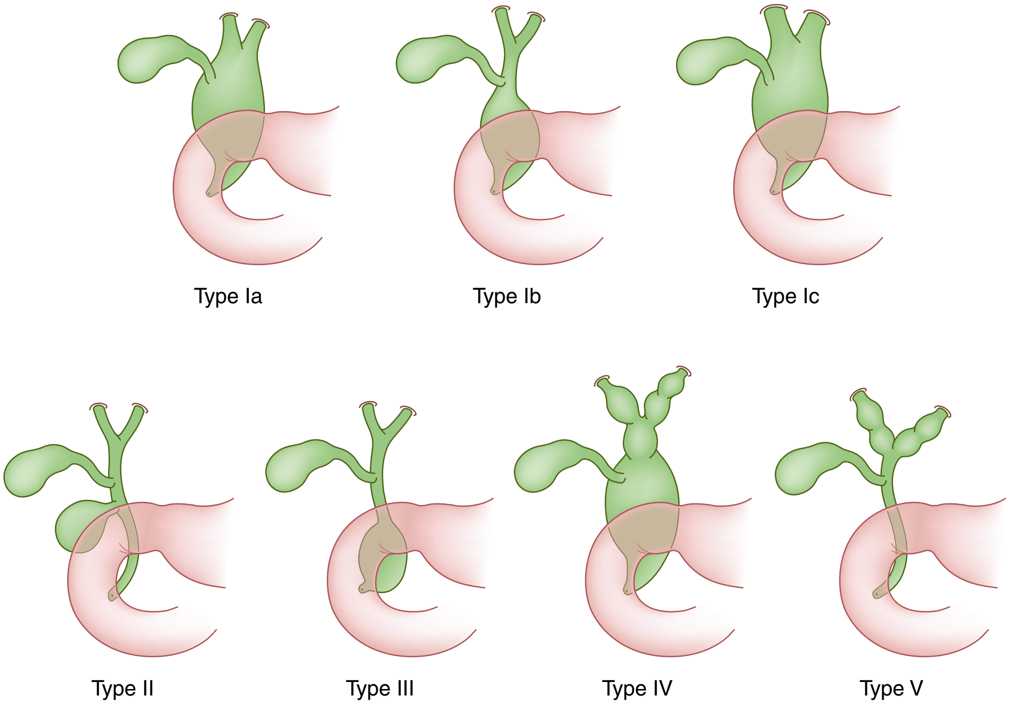

Type Ia Type Ib Type Ic

Type II Type III Type IV Type V

FIGURE 117.16 Classification of choledochal cyst. Anatomic variations of the gallbladder, common bile duct, hepatic ducts and duodenum. (From O'Neill JA. Choledochal cyst. In: Grosfeld JL, O'Neill JA, Fonkalsrud EW, et al., eds. *Pediatric Surgery*. 6th ed. Philadelphia: Mosby Elsevier; 2006:16-21.)

the biliary tree. Choledochoceles represent type III cysts (1.4%–4.5%) and consist of dilation confined to the distal intraduodenal portion of the CBD. Although type IV (15%–35%) involves intrahepatic and extrahepatic bile ducts, type V or Caroli disease (20%) is limited to the intrahepatic ducts only. Choledochal cysts can be associated with other congenital anomalies, including duodenal and colonic atresia, imperforate anus, pancreatic arteriovenous malformation, and pancreatic divisum. Moreover, choledochal cysts are considered premalignant lesions.

The pathogenesis of choledochal cysts is largely unknown, but pancreaticobiliary malunion where pancreatic duct and CBD join with a long common channel (>6 mm) before entry into the duodenum is seen in many cases. This aberrant anatomy leads to bile reflux–induced activation of pancreatic enzymes within the duct that has been implicated. Inflammatory response compromises the integrity of the duct wall, resulting in dilation. In support of this theory, amylase and trypsinogen levels in the bile from patients with choledochal cysts are often elevated. Another possibility is that these cysts arise from CBD obstruction at the sphincter of Oddi.

The classic triad of jaundice, a palpable right upper quadrant mass, and abdominal pain is seen in less than 20% of patients, although 85% present with at least two of these symptoms. Infants typically present with obstructive jaundice and an abdominal mass, whereas older children experience chronic intermittent pain, fever, and jaundice. Complications of cholangitis and pancreatitis can occur as well as bile peritonitis secondary to cyst rupture. Abdominal ultrasound demonstrates a cystic enlarged ductal structure that is separate from the gallbladder. HIDA scan can demonstrate initial absent filling of the cyst, followed by delayed uptake and emptying into the duodenum. MRCP can further define the entire biliary system as well as the pancreatic head. ERCP is rarely necessary to make a surgical decision. Prompt surgical excision of the cysts with Roux-en-Y hepaticojejunostomy is recommended. Complete cyst excision is important because the risk of malignancy is as high as 6% with a retained choledochal cyst. If the complete cyst excision is deemed unsafe due to scarring from chronic inflammation, it should be enucleated. Advocates of the pancreaticobiliary malunion theory will point to separation of biliary and pancreatic drainage with Roux-en-Y hepaticojejunostomy as an important step to arrest the inflammatory process and prevent progression of disease. These patients are monitored with ultrasound examinations postoperatively to ensure adequate drainage of the biliary tree. Postoperative anastomotic strictures are a common complication and likely arise from chronic intrahepatic cholelithiasis and recurrent cholangitis.

Hereditary Pancreatitis and Pancreas Divisum

Hereditary pancreatitis is an autosomal dominant disorder with a high degree of penetrance. It is rare, representing less than 1% of chronic pancreatitis. The disease results from a mutation in the cationic trypsinogen gene *(PRSS1)*, which leads to an increase in the autoactivation of trypsin and resistance to deactivation.[30] The gene has been mapped to chromosome 7q35; the two most common allelic mutations are *R122H* and *N29I.* Recurrent bouts of pancreatitis usually begin in childhood, between 5 and 10 years of age, with no identifiable cause. Aside from the age at onset, the presentation, natural history, diagnosis, and treatment of this disease are similar to those for other causes of pancreatitis. Hereditary pancreatitis should be suspected in any patient who experiences at least two bouts of acute pancreatitis without obvious risk factors, such as trauma, hyperlipidemia, gallstones, or pancreas divisum. It should also be considered in any child with acute pancreatitis and a family history of this disease, as well as pancreatitis in children. Making the correct diagnosis is important because there is an extremely high lifetime risk of malignant transformation. It is estimated that these patients have a fiftyfold to seventyfold increase in the risk for development of pancreatic adenocarcinoma within 7 to 30 years of disease onset. The cumulative lifetime risk is estimated to be 40% by the age of 70. Therefore, screening by endoscopic ultrasound is recommended, starting at the age of 30.

Pancreas divisum is a congenital anatomic anomaly in which the ventral pancreas and dorsal pancreas fail to fuse. The resultant pancreas has dual drainage, with the dorsal pancreas draining through the duct of Santorini and the ventral pancreas (head and uncinate process) draining through the duct of Wirsung. The onset of symptoms is variable, ranging from early childhood to adulthood. Although ultrasound and CT are usually performed, ERCP is frequently used to confirm the diagnosis. However, MRCP has been touted as more advantageous because it can delineate the dorsal pancreatic duct in its entirety, as opposed to ERCP, which can assess only the ventral duct on cannulation of the major duodenal papilla. The significance of pancreas divisum and its predisposition to chronic pancreatitis remains controversial. Some have suggested that it may result in pancreatitis because all pancreatic output is forced to empty through the smaller lesser papilla. The result is an outflow obstruction leading to ductal dilation. Treatment consists of transduodenal sphincteroplasty or a Puestow procedure (pancreaticojejunostomy), which is preferred if the dorsal pancreatic duct is dilated or obstructed.

Biliary Dyskinesia

Obesity has also become a major health problem for adolescents. Subsequently, we are seeing an increasing number of pediatric patients with cholelithiasis and biliary colic due to dyskinesia of the gallbladder. Biliary dyskinesia has become more prevalent and should be considered during the evaluation of a teenager with epigastric pain. Pediatric surgeons are often consulted to evaluate for the appropriateness of performing a cholecystectomy based on a low ejection fraction from a cholecystokinin-stimulated HIDA scan. When an ejection fraction of less than 35% correlates with characteristic biliary colic, a cholecystectomy can be therapeutic.[31] However, in patients with vague symptoms, inconsistent with biliary colic, further examination for the etiology of the pain is warranted before proceeding with cholecystectomy.

ABDOMINAL WALL CONDITIONS

Anterior abdominal wall defects are a relatively frequent neonatal surgical condition. During normal development of the human embryo, the midgut herniates outward through the umbilical ring and continues to grow. By the 11th week of gestation, the midgut returns to the coelomic cavity and undergoes proper rotation and fixation, along with closure of the umbilical ring. If the intestine fails to return, the infant is born with the abdominal contents protruding through the abdominal wall defect at the umbilical ring.

An omphalocele is a central abdominal wall defect that is generally more than 4 cm in diameter, with an intact membranous sac composed of an outer layer of amnion and an inner layer of peritoneum (Fig. 117.17). Defects less than 4 cm in diameter are arbitrarily designated as umbilical cord hernias. Infants with an omphalocele have a high incidence (~50%) of associated anomalies, such as Beckwith-Wiedemann syndrome, which is a combination of gigantism, macroglossia, and an umbilical defect, either a hernia or omphalocele. Chromosomal abnormalities, including trisomies 13, 15, 18, and 21, have also been associated with omphalocele. Other associated anomalies include exstrophy of the bladder or cloaca and the pentalogy of Cantrell, which includes omphalocele; anterior diaphragmatic hernia; sternal cleft; ectopia cordis; and intracardiac defect, such as ventricular septal defect.

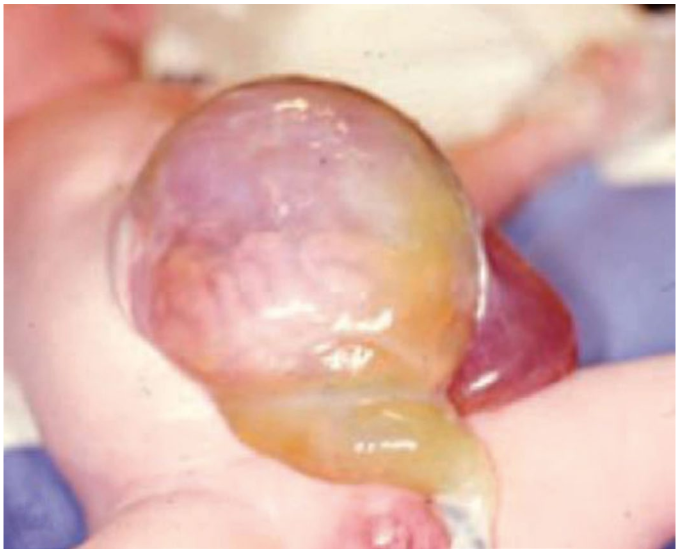

FIGURE 117.17 Omphalocele with intact sac and centrally located abdominal wall defect.

Preservation of an intact omphalocele sac is key in initial management. Also, great care should be taken to prevent hypothermia. A comprehensive diagnostic workup is performed to identify associated anomalies. Primary surgical closure of the small- to medium-sized defect is preferred. Alternatively, larger defects can be closed with prosthetic patch closure (e.g., Gore-Tex), porcine small intestinal submucosa–derived biomaterial (e.g., Surgisis), skin flap closure, or placement of a silo for sequential reduction and staged closure. Giant omphaloceles are treated by topical application of escharotic agents such as povidone-iodine (Betadine) ointment or silver nitrate, which allows the sac to thicken and epithelialize. The overall survival for infants with an omphalocele largely depends on their lung maturity and severity of associated anomalies.

A gastroschisis defect is always to the right of an intact umbilical cord, at the site of obliterated right umbilical vein, without a sac covering the abdominal viscera (Fig. 117.18A). The fascial defect is typically 4 cm in diameter. An absent sac with direct exposure to amniotic fluid in utero results in intestinal thickening and edema with inflammation. Intestinal atresia may exist in up to 15% of cases; however, other major anomalies are rare. Eviscerated bowel must be handled with care to avoid further insult. After birth, infants are placed in a warm, saline-filled plastic “bowel bag” up to the nipple line, to minimize heat and fluid losses. This also allows for gross inspection of the eviscerated bowel at all times and identification of inadvertent twisting of the bowel. Primary reduction is successful in 50% to 80% of cases, with eviscerated contents placed into the abdominal cavity without excessive tension. If primary reduction is unsuccessful, a ringed silo bag is placed and the eviscerated bowel is reduced gradually over several days, followed by operative suture closure of the fascia and skin (see Fig. 117.18B). To avoid compartment syndrome, a safe intraabdominal pressure is less than 15 mm Hg. Alternatively, a sutureless delayed spontaneous closure can be performed at the bedside.[32] Bowel is reduced into the abdomen and the defect is covered with or without the umbilical cord, and

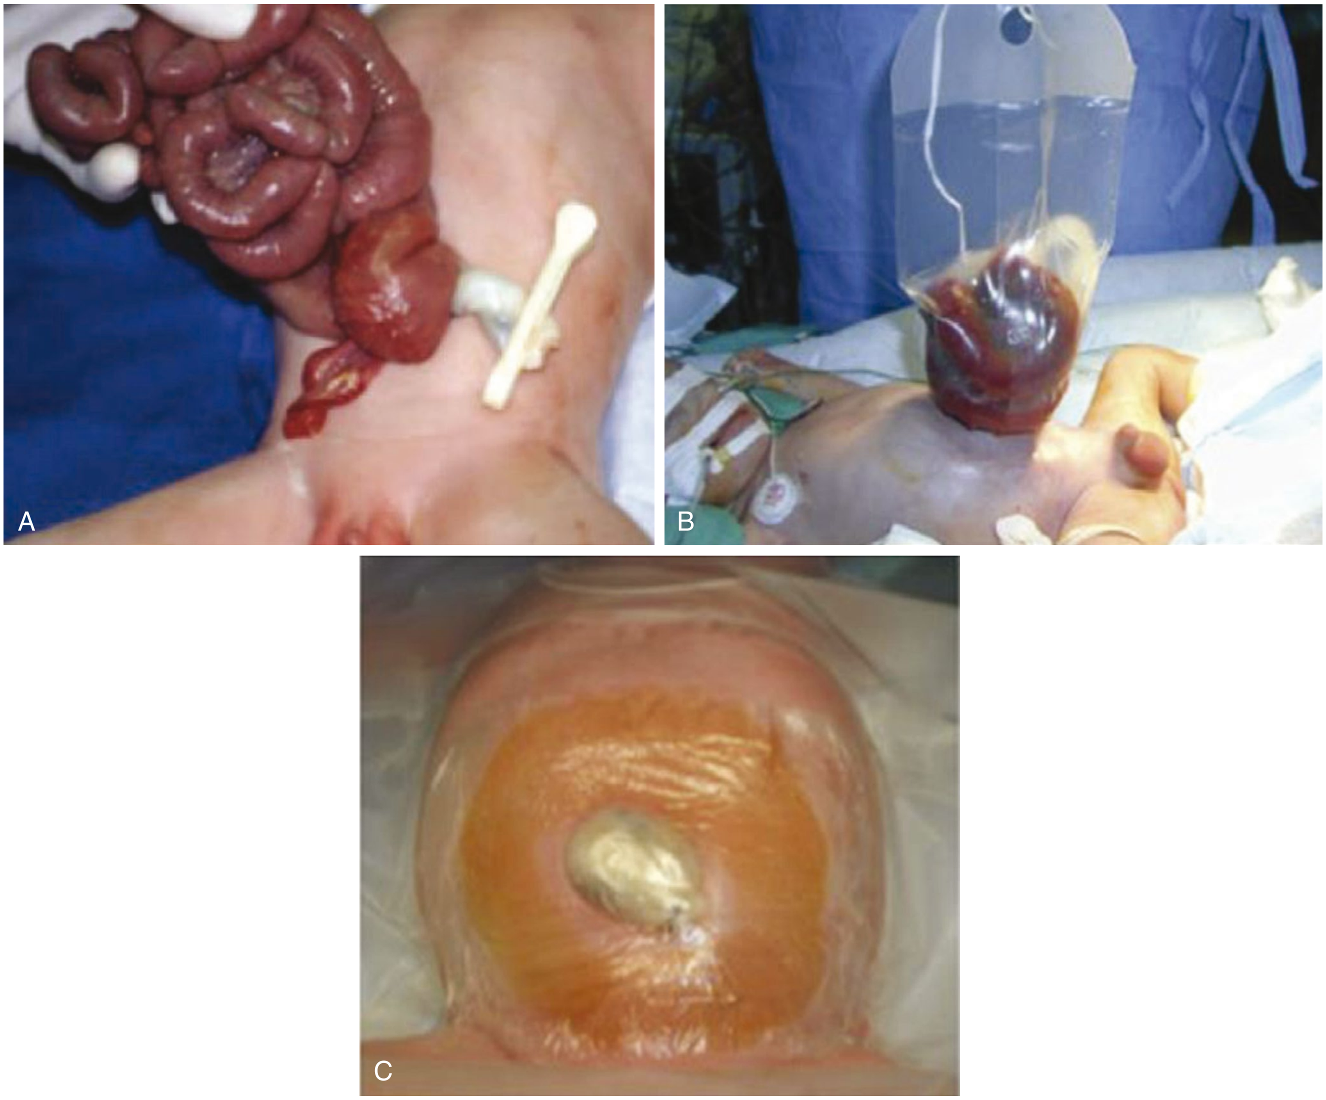

FIGURE 117.18 (A) Gastroschisis with eviscerated multiple bowels. Abdominal wall defect is to the right side of the intact umbilical cord. (B) Silastic bag with ringed edge can be placed at bedside and bowel loops are gradually reduced into abdominal cavity. (C) Sutureless closure of gastroschisis. After reducing eviscerated bowel loops into abdominal cavity, umbilical cord is folded over the defect and a clear watertight dressing is placed.

a watertight clear dressing (see Fig. 117.18C) is placed. Once the contents adhere in the intraabdominal position at around 4 days, the dressing can be changed to a dry dressing over the cord remnant or a Vaseline dressing over the exposed bowel. In cases of associated intestinal atresia or stenosis, inflammation of the bowel precludes an immediate repair; the abdominal wall is closed first, then surgery for intestinal atresia is performed 6 to 8 weeks later. Late occurrence of NEC has been reported in up to 20% of patients after gastroschisis repair. For larger defects, a prosthetic patch (Gore-Tex) is placed and the skin is closed over it. Undescended testis is a common associated finding in 10% to 20% of infants. When found outside the peritoneal cavity, the testes should simply be pushed back into the abdominal cavity without formal orchidopexy at the time of abdominal wall closure or silo bag placement. Many spontaneously descend into the scrotum; if not, then orchidopexy is performed. The majority of infants have prolonged ileus. One of the difficult challenges in the management of gastroschisis remains managing dysfunctional intestine or short gut syndrome and infants often experience cholestasis due to prolonged TPN support.

Hernias

Inguinal hernia repair is one of the most commonly performed surgical procedures in pediatric surgery. The incidence of inguinal hernia is approximately 3% to 5% in term infants and 9% to 11% in premature infants. It affects males approximately six times more often than females. Sixty percent of inguinal hernias occur on the right side, 30% are on the left side, 10% are bilateral, and almost all are indirect and congenital in nature. The processus vaginalis is an elongated diverticulum of the peritoneum that accompanies the testicle on its descent into the scrotum, and it generally is obliterated during the ninth month of gestation or soon after birth. The variable persistence of the processus vaginalis results in a spectrum of clinical presentations, including a scrotal hernia with protrusion of intestine, ovaries, omentum, or communicating hydrocele with intermittent accumulation of peritoneal fluid.

The diagnosis of an inguinal hernia is established by clinical history and examination alone. Transillumination of the scrotum to differentiate a hydrocele from a hernia can be misleading because a herniated, thin-walled loop of bowel in infants and children can be easily transilluminated. Palpation of the cord may elicit a "silk glove sign," which is produced by rubbing the opposing peritoneal membranes of the empty sac. At times, palpation of a thickened cord, compared with the contralateral side, along with a reliable history of intermittent bulge are sufficient to derive a diagnosis. The acute onset of hydrocele may also be associated with other conditions, such as epididymitis, testicular torsion, and torsion of the testicular appendage. In these instances, ultrasound examination may be helpful to determine the diagnosis. The major risks of inguinal hernias are bowel incarceration and potential strangulation. The incidence of incarceration is higher in the first year of life in premature infants.

The ideal timing of inguinal hernia repair in premature infants has recently come under scrutiny. Historically, most advocated for hernia repair before hospital discharge. However, due to concerns of potential complications, including a long-term risk of neurodevelopmental delay with general anesthesia, delayed repair may be a better treatment strategy. There are ongoing multi-institutional studies evaluating the timing of infant inguinal hernia repair. When elective, repair may be deferred until postoperative apnea risk decreases at 1 year of age. An incarcerated inguinal hernia should be reduced first, and repair should be performed 24 to 48 hours later when tissue edema subsides. A nonreducible, incarcerated hernia is a surgical emergency. Contralateral inguinal exploration at the time of symptomatic hernia repair is routinely performed based on the high incidence of a contralateral patent processus vaginalis (4%–65%).

However, the issue regarding the routine exploration of the asymptomatic contralateral side in toddlers remains unresolved. Most pediatric surgeons explore the asymptomatic contralateral side in children 2 years of age or younger. Today, laparoscopic pediatric inguinal hernia repairs are performed with increasing frequency. A recent meta-analysis comparing the laparoscopic versus open approach for pediatric inguinal hernia repair showed no definite advantage of one technique over the other.[33]

An umbilical hernia tends to close on its own in ~80% of cases of children; therefore, elective repair should be deferred until around 5 years of age. Incarceration of an umbilical hernia is extremely rare. Earlier elective surgical repair should be considered when the hernia appears to enlarge over time, or the fascial defect is larger than 2 cm. If left alone, these hernias tend to develop large skin proboscis (>3 cm) resulting in poor postoperative cosmesis. Primary repair of the hernia is always achieved, and the use of prosthetic patch should never be considered.

CHEST WALL DEFORMITY

Pectus excavatum, a chest wall structural deformity where the anterior chest wall is caved in or sunken, is five times more common than pectus carinatum, an abnormal outward protrusion of the anterior chest wall. The deformity is usually present at birth and steadily becomes more prominent with age until past puberty with a male-to-female ratio of 3 to 4:1. Abnormalities in costal cartilage development have been implicated in the underlying pathogenesis. Pectus excavatum can be associated with mitral valve prolapse, Ehlers-Danlos syndrome, and Marfan syndrome; therefore, a comprehensive preoperative evaluation is warranted. The severity of pectus excavatum is quantified by the Haller index, which is a ratio of the width of the chest wall to the depth of between the sternum and the vertebral body on limited chest CT or two-view plain radiographs. In general, a minimum of two of the following criteria are needed to warrant repair: a Haller index of more than 3.25; pulmonary function testing indicating restrictive disease; mitral valve prolapse, murmurs, or conduction abnormalities on echocardiography; physical symptoms from the deformity; or previous failed repair. Psychosocial stress is often significant and should not be underestimated, particularly in adolescents with body image and self-esteem issues. A multicenter study has shown that surgical repair of pectus excavatum significantly improves body image and perceived ability of physical activity.[34] Recent studies have advocated for the use of the correction index (CI), which quantifies the percentage of chest depth to be regained by surgical correction. Most authors advocate for surgical repair with a CI of 28% or higher, but this is still controversial.

The optimal age for pectus excavatum repair is 10 to 14 years of age. The Nuss procedure has largely replaced the Ravitch (open) procedure for most cases of pectus excavatum. Under thoracoscopic guidance, a tunneler is used to perform the retrosternal dissection. Sternal elevation using a retractor system has become popularized for a safer sternal dissection in recent years. An appropriately sized titanium bar is bent and contoured to elevate the sternum, and the bar is passed through the retrosternal plane from one hemithorax into the other, through two lateral intercostal incisions (Fig. 117.19). The Nuss bar is then flipped so that the convexity is outward, and the chest wall defect is immediately corrected. The bar is removed after ~2 years. The Ravitch procedure involves detachment of the costal bundles with removal of the malformed costal cartilages and fracture of the sternum to restore normal chest contour. The costal bundles are then reattached, and the sternum is held in the desired position using a bar, which is removed in 6 months. The use of enhanced recovery pathways after surgery and utilization of intercostal nerve cryoablation has significantly shortened postoperative hospital length of stay to <2 days.[35] Pectus carinatum is typically corrected with a fitted chest brace or Ravitch procedure. There are several different models, but the most important predictor of success is treatment adherence, which requires continuous use for 14 to 16 hours daily to see the best results. Before the use of current enhanced recovery after surgery (ERAS) pain management pathways, postoperative pain was a significant consideration for patients undergoing surgical correction and the historic indications for surgery reflected this. With these protocols, more patients are being considered for surgical correction of pectus deformities than in the past.

GENITOURINARY TRACT CONDITIONS

Cryptorchidism

Cryptorchidism is a condition in which one or both testes fail to descend into the scrotum before birth. Although up to 30% of preterm infants can present with an undescended testis, it also occurs in ~23% of full-term infants. Some undescended testes eventually descend by 1 year of age. The undescended testis is associated with histologic and morphologic changes as early as 6 months of age, whereas atrophy of Leydig cells, a decrease in tubular diameter, and impaired spermatogenesis can occur by 2 years of age. An undescended testis has had its descent halted somewhere along the path of normal descent and is most commonly located in the inguinal canal. A retractile testis is a normally descended testis that retracts into the inguinal canal due to

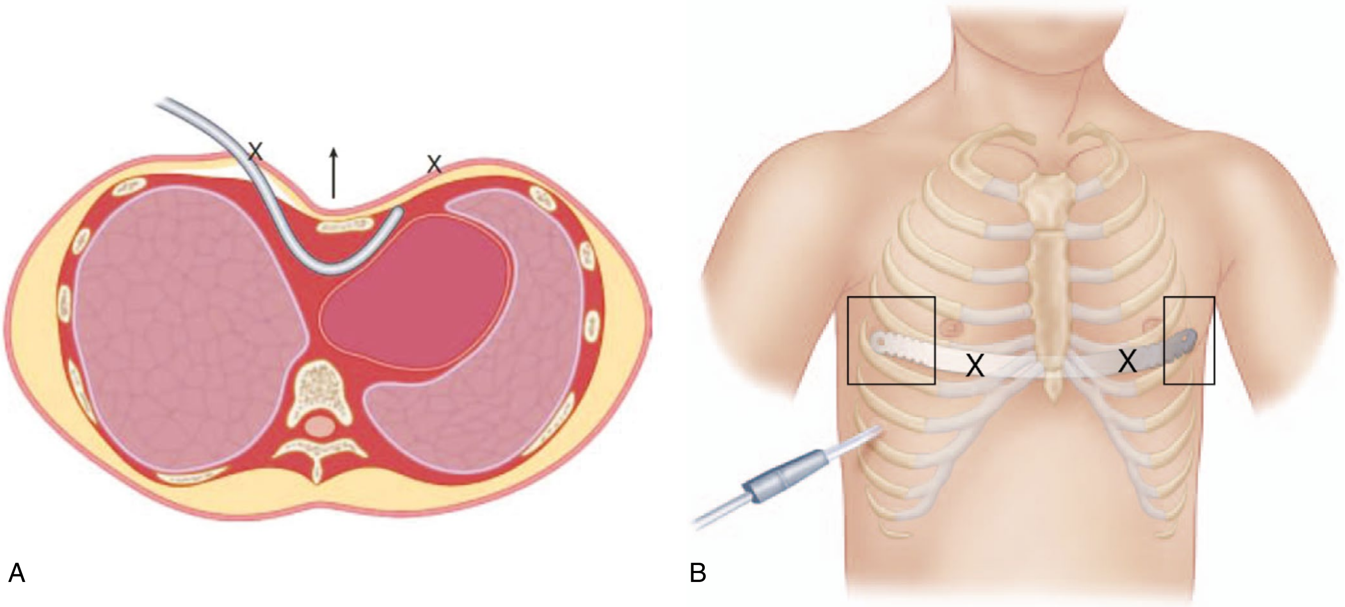

FIGURE 117.19 (A) Pectus excavatum. A tunneler is used to dissect retrosternal place under thoracoscopic guidance. (B) A Nuss bar is placed beneath the sternum and secured onto the chest wall with stabilizers. (From Goretsky MJ, Nuss D. Surgical treatment of chest wall deformities: Nuss procedure. hyperreflexive cremasteric muscle; it is easily brought down into the scrotal sac during the examination and does not require operative intervention. Nonpalpable testes may include an intraabdominal, absent, or vanishing testis. Ectopic testes have had an aberrant path of descent, and these can be found in the perineum, femoral canal, and suprapubic regions. For unilateral palpable testis in the inguinal canal, standard dartos pouch orchidopexy is performed at 6 to 12 months of age. An algorithm for management of nonpalpable testes is shown in Fig. 117.20. For nonpalpable, undescended testis, a diagnostic laparoscopy is useful. If the testicular vessels are seen exiting the internal ring, an open inguinal orchidopexy is performed. For an intraabdominal testis, a two-stage Fowler-Stephens orchidopexy is considered, in which the testicular vessels are ligated as a first stage to allow for development of collateral circulation over 6 months before orchidopexy is performed as a second-stage procedure. Laparoscopic orchidopexy has become popularized as an ideal single-stage option, allowing for full mobilization of the testicular vessels to the level of the base of the kidney. If both testes are nonpalpable, a human chorionic gonadotropin (hCG) stimulation test is carried out to confirm the presence of functioning testes. If present, diagnostic laparoscopy can locate the testes. The risk of malignancy has been reported to be significantly higher (four to five times increased risk) for males with a history of undescended testes. Orchidopexy does not decrease the malignancy risk associated with undescended testes, but it allows for earlier detection. Seminomatous germ cell tumors are the most common tumor type with undescended testes.

Testicular Torsion

Torsion of the testis occurs in two distinct patient populations: neonates (approximately 8%–10%) and adolescents and young adults (approximately 90%). Extravaginal torsion is more common in neonates where torsion of the spermatic cord occurs along its course outside the tunica vaginalis. Intravaginal torsion is typical in adolescents and young adults and is associated with a bell clapper deformity in which the long suspensory ligaments of the testis can twist. It is important to distinguish the etiology of the two types of torsion because they do have different management pathways. Neonatal (extravaginal) torsion is typically an in utero event and, as such, not a surgical emergency. The testis is typically not viable, and orchiectomy is necessary. Because this is due to a problem with testicular descent, and not associated with an anatomic abnormality, contralateral exploration and orchiopexy is not indicated. Neonates typically present with a firm, darkened hemiscrotum with minimal tenderness. In contrast, the more common adolescent or young adult (intravaginal) torsion is a surgical emergency with the possibility to salvage the testicle. Because this is due to an anatomic abnormality of the suspensory ligament of the testis, contralateral exploration and orchiopexy is indicated as this anomaly is present bilaterally.

Acute onset, severe testicular pain is the primary symptom in adolescents and young adults. After torsion, the testis may be high riding, edematous, and significantly tender. Urinary tract symptoms of frequency, urgency, and dysuria tend to occur more common with an infectious or inflammatory etiology, such as epididymitis; however, the presence of urinary symptoms does not rule out testicular torsion. In most, a careful history and physical examination are sufficient to confirm the diagnosis of testicular torsion. If the diagnosis is uncertain, ultrasonography may be helpful to determine the presence of vascular flow to the testicles; however, radioisotope scanning is the most specific diagnostic test. Immediate surgical detorsion through a scrotal medial raphe approach is the standard operation. After detorsion, the testis is assessed for viability and fixed to the scrotum. Importantly, the contralateral testis is explored and fixed in adolescents and young adults. The time between establishing the diagnosis and the surgical detorsion directly correlates with the testicular salvage rate. For torsion of less than 6 hours, 90% of testes can be salvaged. The salvage rate for testis decreases to less than 10% with longer than 24 hours of symptoms.

Testicular Tumors

Testicular cancer accounts for less than 2% of all pediatric solid tumors and has bimodal peaks at around 2 years of age and at puberty. Testicular tumors commonly present as painless scrotal masses, often discovered incidentally. Ultrasonography is useful, but CT scan is critical for evaluation of retroperitoneal lymphadenopathy as well as metastatic disease. The serum tumor marker α-fetoprotein (AFP), a glycoprotein produced by the fetal yolk sac, is elevated in yolk sac tumors. β-hCG is produced by embryonal carcinomas and mixed teratomas. There are two main types of testicular tumors, germ cell and non–germ cell. Germ cell tumors are subdivided into seminomas and nonseminomatous tumors, (embryonal carcinoma, yolk sac carcinoma, choriocarcinoma, and teratoma) and comprise over 95% of all testicular tumors. Non–germ cell tumors, also known as *stromal tumors,* are further divided into Sertoli and Leydig cell tumors and comprise less than 5% of all testicular tumors. The surgical strategy is radical inguinal orchiectomy. Tumors with microscopic or gross nodal involvement require systemic chemotherapy, with modified retroperitoneal lymphadenectomy. The 5-year survival for patients with localized, regional, or distant metastatic testicular germ cell tumors is 99.2%, 96%, and 73%, respectively. In contrast, although 5-year survival rates for stage I non–germ cell tumors are approximately 80% to 90%, the prognosis for metastatic disease is poor with median survival between 1 and 2 years.

PEDIATRIC SOLID TUMORS

Neuroblastoma

Arising from neural crest cells, neuroblastoma is a malignant neoplasm of the sympathetic nervous system. It occurs most commonly in the abdomen (65%), then chest (20%), followed by neck (5%) and pelvis (5%); they account for 8% to 10% of all childhood cancers. They are often found incidentally and present with minimal clinical symptoms. Thoracic tumors are discovered at the time of routine chest radiograph obtained for unrelated respiratory symptoms. Pelvic masses may cause constipation or bladder dysfunction due to extrinsic mass effects. Horner syndrome may develop in 15% of patients with neck tumors that compress the sympathetic ganglia. If tumors extend into the spinal column, significant neurologic deficits occur and rapidly progress to paralysis. Half of these patients have localized disease at diagnosis; 35% have regional lymph node involvement. For bone marrow invasion, patients may experience anemia, bruising, and weakness as well as bone pain, swelling, limping, or pathologic fractures. Periorbital swelling and proptosis (raccoon eyes) indicate the involvement of orbits. Blue subcutaneous nodules represent skin dissemination of tumors associated with the blueberry muffin syndrome. Paraneoplastic syndromes can produce intractable diarrhea caused by vasoactive intestinal peptide secretion, encephalomyelitis, and neuropathy. Opsoclonus-myoclonus syndrome (rapid, conjugate eye nystagmus with involuntary spasms of the limbs) although rare, occurs when antibodies cross-react with cerebellar tissue.

Neuroblastoma occurs as whole chromosome gains, which result in hyperdiploidy and are associated with a favorable prognosis, or segmental chromosomal aberrations, which encompass *MYCN* amplification and gains or losses that tend to be associated with worse outcomes. The *MYCN* oncogene, which is amplified at chromosome 2p24 in 25% of cases, is found in 30% to 40% of advanced-stage neuroblastomas but only in 5% of localized or stage 4S tumors. Deletion of the 1p36 region occurs in 70% and is usually associated with *MYCN*-amplified, high-risk neuroblastomas that confer a poor prognosis. Deletions of chromosome 11q are noted in 15% to 22% of cases and indicate an unfavorable outcome. Conversely, a whole chromosome 17 gain is associated with a good prognosis.

Elevated urine catecholamines and their metabolites (dopamine, vanillylmandelic acid, homovanillic acid) are pathognomonic for neuroblastoma in infants and toddlers. Elevated lactate dehydrogenase (>1500 U/mL), ferritin (>142 ng/mL), and neuron-specific enolase (>100 ng/mL) can be indicative of neuroblastoma but are nonspecific. Cross-sectional imaging shows characteristic calcifications within the tumor (Fig. 117.21). An MRI is helpful to detect spinal cord extension. ^{131}I-metaiodobenzylguanidine (MIBG) scan is particularly valuable in the detection

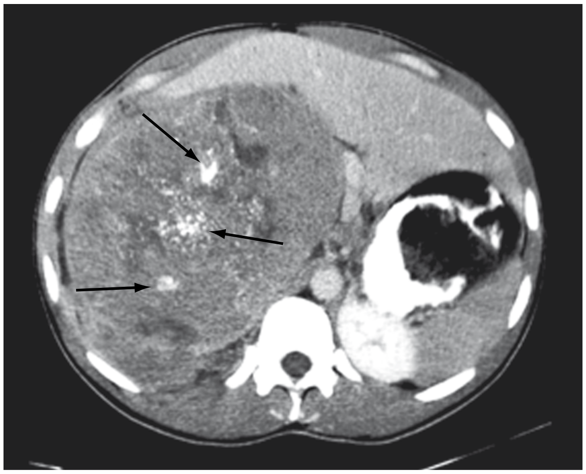

FIGURE 117.21 CT scan of neuroblastoma demonstrating areas of calcification *(arrows)*. (From Kim S, Chung DH. Pediatric solid malignancies: Neuroblastoma and Wilms' tumor. *Surg Clin North Am*. 2006; 86:469-487.)

of metastases because the norepinephrine analogue is selectively concentrated in sympathetic tissue. The^{131} I-MIBG scan is also used for the surveillance of treatment response and recurrence. Poorly differentiated small round blue cells are classic histopathologic features. Although localized tumors can be resected up front, many present as advanced-stage tumors with extensive disease involving vital structures. They should undergo an initial biopsy for analysis of tumor biology. After induction chemotherapy, complete resection or debulking achieving >90% resection offers the best overall disease-free and survival chances.[36] DNA ploidy, *MYCN* amplification, and other chromosomal abnormalities are analyzed routinely. Neuroblastoma can be classified on the basis of neuroblastic differentiation and mitosis-karyorrhexis index (low, intermediate, or high), and the presence of Schwann cells. Children's Oncology Group currently stratifies patients into low-, intermediate-, or high-risk categories on the basis of the patient's age at diagnosis, International Neuroblastoma Staging System (INSS) stage, tumor histopathology, DNA index, and *MYCN* amplification status.[37]

Image-defined risk factor (Table 117.1) after neoadjuvant therapy is useful in predicting the completeness of neuroblastoma resection.[38] The multimodality treatment strategy is based on disease risk group stratification (Table 117.2). Induction chemotherapy consists of a multidrug regimen, including but not limited to cyclophosphamide, doxorubicin, cisplatin, carboplatin, etoposide, and vincristine. However, high-risk group neuroblastomas frequently acquire resistance to chemotherapeutics and thus have high disease relapse. This usually necessitates autologous hematopoietic stem cell transplantation. Complete surgical resection correlates with a lower local recurrence, especially in combination with induction chemotherapy, local radiation, and immunotherapy.

Primary surgical resection is recommended for stage 1 to 2B tumors. For more advanced stage 3 and 4 tumors, only the incisional biopsy specimen is obtained initially for tumor biology studies. The role of aggressive surgical resection of the primary tumor site for metastatic stage 4 neuroblastoma in patients 18 months or older remains the standard therapy in the United States.[36] For infants with stage 4S disease, surgical resection is not recommended because of the high rate of spontaneous differentiation and regression. For high-risk patients, radiation therapy is often needed for local and metastatic control. Radiation is contraindicated for intraspinal tumors because it can lead to vertebral damage, growth arrest, and scoliosis. However, it may be necessary

TABLE 117.1 Image-Defined Risk Factor in Neuroblastoma

TUMOR LOCATION	CRITERIA
Tumor involving two body compartments	Neck-chest, chest-abdomen, abdomen-pelvis
Neck	Tumor encasing carotid and/or vertebral artery and/or internal jugular vein
	Tumor extending to base of skull
	Tumor compressing the trachea
Cervicothoracic	Tumor encasing brachial plexus roots
	Tumor encasing subclavian vessels and/or vertebral and/or carotid artery
	Tumor compressing the trachea
Thorax	Tumor encasing the aorta and/or major branches
	Tumor compressing the trachea and/or principal bronchi
	Lower mediastinal tumor, infiltrating the costovertebral junction between T9 and T12
Thoracoabdomen	Tumor encasing the aorta and/or vena cava
Abdomen/pelvis	Tumor infiltrating the porta hepatis and/or the hepatoduodenal ligament
	Tumor encasing branches of the superior mesenteric artery at the mesenteric root
	Tumor encasing the origin of the coeliac axis, and/or of the superior mesenteric artery
	Tumor invading one or both renal pedicles
	Tumor encasing the aorta and/or vena cava
	Tumor encasing the iliac vessels
	Pelvic tumor crossing the sciatic notch
Intraspinal	More than one-third of the spinal canal in the axial plane is invaded and/or the perimedullary leptomeningeal spaces are not visible and/or the spinal cord signal is abnormal
Infiltration of adjacent structure	Pericardium, diaphragm, kidney, liver, duodenopancreatic block, and mesentery
Conditions recorded but not IDRFs	Multifocal primary tumors
	Pleural effusion, with or without malignant cells
	Ascites, with or without malignant cells

*IDRF*s, Image-defined risk factors.

TABLE 117.2 International Neuroblastoma Risk Group Pretreatment Classification

INRG STAGE	AGE (MO)	HISTOLOGIC CATEGORY	GRADE	*MYCN*	11Q	PLOIDY	RISK GROUP	5-YEAR EFS
L1/L2		GN, GNB intermixed					Very low	>85%
L1		Any, except GN/GNB		NA			Very low	>85%
				Amp			High	<50%
L2	<18	Any, except GN/GNB		NA	No		Low	>75% to ≤85%
					Yes		Intermediate	≥50% to ≤75%
	≥18	GNB nodular, neuroblastoma	Differentiating	NA	No		Low	>75% to ≤85%
			Poorly differentiated or undifferentiated	NA	Yes		Intermediate	≥50% to ≤75%
				Amp			High	<50%
M	<18			NA		Hyperdiploid	Low	>75% to ≤85%
	<12			NA		Diploid	Intermediate	≥50% to ≤75%
	12–<18			NA		Diploid	Intermediate	≥50% to ≤75%
	<18			Amp			High	<50%
	≥18						High	<50%
MS	<18			NA	No		Very Low	>85%
				Amp	Yes		High	<50%
							High	<50%

L1, Localized tumor not involving vital structures as defined by the list of image-defined risk factors and confined to one body compartment; *L2,* locoregional tumor with presence of one of more image-defined risk factors; *M,* distant metastatic disease (except stage MS); *MS,* metastatic disease in children younger than 18 months with metastasis confined to skin, liver and/or bone marrow.

Amp, Amplified; *EFS*, event-free survival; *GN*, ganglioneuroma; *GNB*, ganglioneuroblastoma; *INRG,* International Neuroblastoma Risk Group; *NA*, nonamplified.

for palliation in the setting of pain, hepatomegaly with respiratory compromise, or acute neurologic symptoms caused by tumor compression of the cord. It is further indicated when there is minimal residual disease after induction chemotherapy and resection. The overall outcomes in patients with neuroblastoma have improved steadily during the past decades, with 5-year survival rates rising from 52% to 74%. The low-risk group has shown significant improvement in survival rates of up to 92%. It is estimated that 50% to 60% of the high-risk group relapse after standard therapy. Anti-GD2 immunotherapy has become a standard therapy for children with high-risk disease.[37]

Wilms Tumor

Wilms tumor (WT), also known as nephroblastoma, is an embryonal renal neoplasm consisting of metanephric blastema; it accounts for 85% of cases. WT represents 5.9% of all pediatric malignant tumors and ~75% are diagnosed in children <5 years of age. Bilateral tumors are noted at diagnosis in 13%. A number of syndromes can predispose to the development of WT such as Beckwith-Wiedemann (macroglossia, macrosomia, midline abdominal wall defects, and neonatal hypoglycemia), Li-Fraumeni (*p53* germline mutation with predisposition to various cancers), and Denys-Drash (gonadal dysgenesis, nephropathy, and WT) syndromes and neurofibromatosis. In 10% of patients, WT can be associated with other congenital anomalies, collectively known as WAGR syndrome (aniridia, hemihypertrophy, genitourinary malformations, and mental retardation).

The WT suppressor gene, *WT1,* is located on chromosome 11p13, which contains genes responsible for the development of the kidney, genitourinary tract, and eyes. Mutations in *WT1* result in genitourinary abnormalities, such as cryptorchidism and hypospadias, but also increase the risk for development of WT. Aniridia is found in 1.1% of WT patients, and when *WT1* deletions are found in these patients, there is a 40% rate of WT development. Moreover, mutations in *WT2,* located at 11p15, have been linked to Beckwith-Wiedemann syndrome, and there is a 4% to 10% risk for development of WT in those who also have hemihypertrophy. WT is typically discovered incidentally during a physical examination or parents having felt an abdominal mass. Other presenting symptoms include vague abdominal discomfort and hematuria, which may signify tumor invasion into the collecting system or ureter. Hypertension is present in 25% of patients and is thought to occur secondary to disturbances in the renin-angiotensin feedback loop. Less than 10% of patients have atypical symptoms such as varicocele, hepatomegaly caused by hepatic vein obstruction, ascites, and congestive heart failure.

Tumor thrombus into the renal vein or IVC is detected by ultrasound study. A CT scan is valuable in determining WT from other tumors and also to evaluate for regional adenopathy, contralateral kidney involvement, and distant organ metastasis. Lung metastases are present in 8% at the time of diagnosis. The histology of WT is categorized as favorable or unfavorable. Favorable histology is characterized by the presence of three elements: blastemal, stromal, and epithelial cells. WT with predominantly epithelial differentiation behaves less aggressively and tends to be stage I when it is diagnosed early. Blastemal-predominant tumors tend to be clinically aggressive and are associated with advanced disease. Outcomes correlate with histopathologic features and tumor stage. Unfavorable histology is characterized by anaplasia, clear cell sarcoma, or rhabdoid tumor. Anaplastic WT can be focal or diffuse and carries an increased risk of tumor recurrence and chemoresistance. Nephrogenic rests are precursor lesions found in 25% to 40% of kidneys with WT but do not have oncologic potential. Instead, they can undergo differentiation and spontaneously regress through unclear mechanisms.

TABLE 117.3 National Wilms Tumor Study Group Staging System

STAGE	DEFINITION
I	Tumor limited to the kidney and completely excised without rupture or biopsy. Surface of the renal capsule is intact
II	Tumor extends through the renal capsule but is completely removed, with no microscopic involvement of the margins. Vessels outside the kidney contain tumor. Also placed in stage II are cases in which the kidney has undergone biopsy before removal or where there is local spillage of tumor (during resection) limited to the tumor bed
III	Residual tumor is confined to the abdomen and of nonhematogenous spread. Includes tumors with involvement of the abdominal lymph nodes, diffuse peritoneal contamination by rupture of the tumor extending beyond the tumor bed, peritoneal implants, and microscopic or grossly positive resection margins
IV	Hematogenous metastases at any site
V	Bilateral renal involvement

The International Society of Pediatric Oncology (SIOP) staging system is based on preoperative chemotherapy but is applied after resection. The presence of metastases is evaluated at presentation, relying on images, and chemotherapy is administered before operative intervention. The National Wilms Tumor Study Group (NWTSG) has also developed a staging system that incorporates the clinical, surgical, and pathologic information obtained at the time of resection but stratifies patients before the initiation of chemotherapy (Table 117.3). The advantage of this system is that it favors stage-based therapy, thereby avoiding unnecessary chemotherapy in patients who might not otherwise benefit from it.

The mainstay of therapy for WT is surgery and chemotherapy. Surgical exploration is necessary for formal staging, and a radical nephrectomy with lymph node sampling is the standard operation. Utmost care must be taken to ensure en bloc resection with tumor-free margins because contamination and tumor spillage "upstages" the patient and would require postoperative radiation and additional chemotherapy. Vascular tumor extension into the IVC constitutes stage III disease and is managed accordingly (Fig. 117.22). Sampling of the hilar, paraaortic, and paracaval lymph nodes is essential. Nephron-sparing surgery is usually reserved for children with a solitary kidney or bilateral WT. In these patients, preoperative chemotherapy may be used to induce tumor shrinkage to allow a more complete resection. Partial nephrectomy may be considered if the tumor involves only one pole of the kidney, there is no evidence of collecting system or vascular involvement, clear margins exist between the tumor and surrounding structures, and the involved kidney demonstrates appreciable function. In Stage V WT biopsy confirmation at diagnosis is not necessary. According to the NWTSG guidelines (Box 117.2), the standard chemotherapy regimen consists of vincristine and dactinomycin, with the addition of doxorubicin or radiation therapy based on tumor stage and histologic favorability. The SIOP advocates the use of preoperative chemotherapy to improve cure and disease-free survival rates at 5 years. Stages I or II favorable histology or stage I unfavorable histology has a nearly 95% survival rate. For WT with unfavorable histology, stages II, III, and IV are associated with 70%, 56%, and 17% 4-year survival rates, respectively.

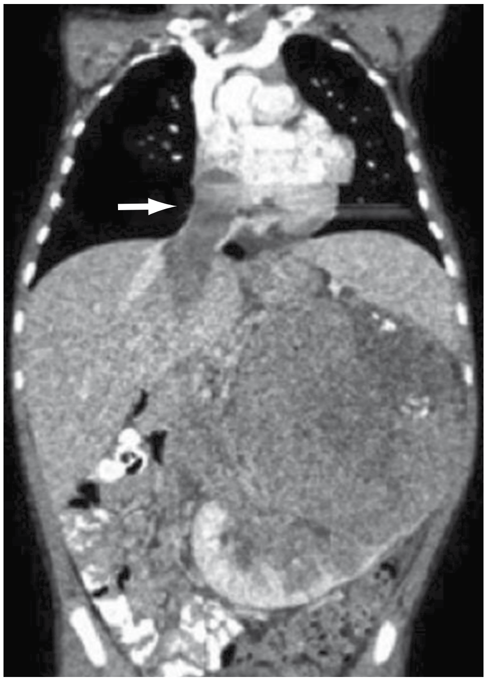

FIGURE 117.22 CT image of Wilms tumor with a claw sign and a large inferior vena cava tumor thrombus extending to right atrium *(arrow)*.

Rhabdomyosarcoma

Derived from embryonic mesenchymal cells that can later differentiate into skeletal muscle, rhabdomyosarcoma is a soft tissue malignant neoplasm that accounts for 4% of all pediatric cancer. There is a bimodal peak age at diagnosis, between the ages of 2 and 5 years and 15 and 19 years. Rhabdomyosarcoma is known to occur with increased frequency in patients with neurofibromatosis type I and Li-Fraumeni and Beckwith-Wiedemann syndromes. Rhabdomyosarcoma is classified into three types: embryonal, alveolar, and pleomorphic. Embryonal rhabdomyosarcoma, which

BOX 117.2 Treatment Regimens for Wilms Tumor[a]

- Stage I (FH, focal anaplasia): Surgery, VA × 18 wk, no XRT
- Stage II (FH): Surgery, VA × 18 wk, no XRT
- Stage II (focal anaplasia): Surgery, VDA × 24 wk, XRT to tumor bed
- Stage III (FH, focal anaplasia): Surgery, VDA × 24 wk, XRT to tumor bed
- Stage III (focal anaplasia): Surgery, VDA × 24 wk, XRT to tumor bed
- Stage IV (FH; focal anaplasia): Surgery, VDA × 24 wk, XRT to tumor bed according to local tumor stage and lung or other metastatic sites
- Stages II–IV (diffuse anaplasia): Surgery, VDEC × 24 wk, XRT to whole lung and abdomen
- Stages I–IV (clear cell sarcoma): Surgery, VDEC × 24 wk, XRT to abdomen; XRT to whole lung for stage IV only
- Stages I–IV (rhabdoid tumor): Surgery, ECCa × 24 wk, XRT

[a]National Wilms Tumor Study. Infants younger than 11 months are given half the recommended dose of all drugs.
A, Dactinomycin; *C,* cyclophosphamide; *Ca,* carboplatin; *D,* doxorubicin; *E,* etoposide; *FH,* favorable histology; *V,* vincristine; *XRT,* radiation therapy.

includes botryoid and spindle cell subtypes, is the most common type, accounting for more than two-thirds of all rhabdomyosarcomas. Muscle-specific proteins, myosin, actin, desmin, and myoglobin, are stained for immunohistochemical diagnosis.

The common sites for rhabdomyosarcomas are in the head and neck (35%), genitourinary tract (25%), and extremities (20%). Head and neck tumors tend to occur in the parameningeal region, orbits, and pharynx. Other specific sites include the bladder, prostate, vagina, uterus, liver, biliary tract, paraspinal region, and chest wall. These tumors are generally asymptomatic, although most symptoms are related to extrinsic tumor effects. Orbital tumors can produce proptosis, decreased visual acuity, and ophthalmoplegia. Those arising from parameningeal sites frequently produce headaches and nasal or sinus obstruction that can be accompanied by a mucopurulent or bloody discharge. For genitourinary rhabdomyosarcoma, paratesticular tumors may present as painless swelling in the scrotum, which may be confused for a hernia, hydrocele, or varicocele. Bladder tumors, commonly located at the base and trigone, result in hematuria and urinary obstruction. Vaginal tumors in females present with a protruding mass or vaginal bleeding and discharge. In the extremities, rhabdomyosarcomas involve the distal limb more commonly, and the lower extremities are affected more often. At diagnosis, 50% of patients have regional lymph node metastasis. Retroperitoneal tumors can be quite large at diagnosis with symptoms arising secondary to invasion of adjacent structures.

There are no specific serum tumor markers for rhabdomyosarcoma. MRI or CT demonstrates the mass and its involvement of adjacent structures, vessel encasement, metastasis, and adenopathy. An incisional or core-needle biopsy is crucial to achieve a diagnosis. A complete surgical resection is ideal, but a large tumor may necessitate preoperative chemotherapy for tumor shrinkage. As RMS is chemosensitive, and radiosensitive, aggressive up-front resections are not necessary. Biopsy followed by chemotherapy is the primary preferred approach. Botryoid (cluster of grapes) and spindle cell rhabdomyosarcomas have favorable prognosis, whereas pleomorphic histology confers an intermediate prognosis, and alveolar type exhibits a poor prognosis. Pretreatment staging, based on tumor-node-metastasis (TNM) criteria, serves to stratify patients into the appropriate treatment regimen, and to compare outcomes (Box 117.3). Intraoperative or pathologic results from resected samples are used for clinical grouping, which consists of selection into a group depending on operative findings, pathology, margins, and node status. Estimated 3-year failure-free survival rates are 88%, 55% to 76%, and <30% for low-risk, intermediate-risk, and high-risk patients, respectively.

BOX 117.3 Staging for Rhabdomyosarcoma

Group I: Localized disease that is completely resected, with no regional node involvement

Group II

A. Localized, grossly resected tumor with microscopic residual disease but no regional nodal involvement

B. Locoregional disease with tumor-involved lymph nodes with complete resection and no residual disease

C. Locoregional disease with involved nodes, grossly resected, but with evidence of microscopic residual tumor at the primary site and/or histologic involvement of the most distal regional node (from the primary site)

Group III: Localized, gross residual disease including incomplete resection or biopsy only of the primary site

Group IV: Distant metastatic disease present at time of diagnosis

The main goal of multimodality therapy is to achieve cure or to obtain local control. The recommended chemotherapy regimen depends on the risk stratification, with low-risk patients in subgroup A receiving vincristine and dactinomycin. Cyclophosphamide is added to this therapy for patients in the low-risk subgroup B and higher. Radiation therapy has been found to be effective for the local control of rhabdomyosarcoma, especially in patients who have microscopic disease after resection as well as in patients with unresectable tumors. For extremity lesions, it is imperative to achieve complete wide local excision. Amputation is rarely necessary, except for distal tumors in the hand or foot that involve neurovascular structures. Given that trunk and extremity lesions have a high incidence of lymph node metastasis, sentinel lymph node mapping is being increasingly used. Reexcision may also be considered with evidence of minimal residual disease after initial resection. Patients with extremity tumors receive combination chemotherapy, but because of the high incidence of the alveolar histology, radiation therapy is also often used. For genitourinary tumors, preservation of bladder function is the key in resection of tumors involving the bladder or prostate. If this goal cannot be met, preoperative chemoradiation is usually recommended. Paratesticular rhabdomyosarcoma should undergo a radical inguinal orchiectomy, with a retroperitoneal lymph node dissection in males younger than 10 years because of the high prevalence of metastasis. When the tumor is clearly fixed to scrotal skin, resection is required. Chemotherapy is standard, whereas radiation therapy is indicated only with positive nodes. For patients with vaginal or vulvar rhabdomyosarcoma, vaginectomy and wide local excision, respectively, and multiagent chemotherapy are recommended. Approximately 15% of children present with metastatic disease, and their prognosis remains poor. Nearly 30% will experience disease relapse, and the estimated 5-year survival rate is only 17%. Despite these harrowing data, however, rhabdomyosarcoma is a curable disease in most children, with more than 60% surviving 5 years after diagnosis.

Liver Tumors

Primary tumors of the liver are rare in the pediatric population but are malignant in approximately 60% of cases. The two most common tumors are hepatoblastoma and hepatocellular carcinoma (HCC). Hepatoblastoma represents 80% of all malignant liver tumors and 1% of all pediatric cancer. The peak incidence of hepatoblastoma is at 3 years of age; the median age for children with HCC is 10 to 11.2 years. More than 90% of patients younger than 5 years with primary liver tumors have hepatoblastoma, whereas 87% of those between 15 and 19 years have HCC. Patients with familial adenomatous polyposis, Gardner, and Beckwith-Wiedemann syndromes are at increased risk for the development of hepatoblastoma. HCC is associated with acquired hepatitis B and C and has been observed in children with several types of congenital diseases, including tyrosinemia, glycogen storage disease type I, α_1-antitrypsin deficiency, and cholestasis caused by BA.

Hepatoblastoma typically manifests as a painless, palpable abdominal mass. Other symptoms are nonspecific and include anorexia, weight loss and failure to thrive, abdominal pain, anemia, and abdominal distention. Jaundice is not commonly encountered because liver function remains relatively normal except in a very advanced tumor. Some patients present with tumor rupture, resulting in intraabdominal bleeding and peritonitis. HCC is manifested similarly, although stigmata of cirrhosis, such as jaundice, spider angiomas, ascites, and splenomegaly, may be encountered. Almost 25% of patients have metastatic spread to abdominal and mediastinal lymph nodes, lung, bone marrow, and brain. Anemia, thrombocytopenia, or pancytopenia can be found with splenomegaly caused by sequestration. AFP levels are elevated in more than 70% of hepatoblastoma patients. However, an elevated AFP level is not pathognomonic, and depending on the age of the patient, other disease processes must be ruled out. For example, in infants younger than 6 months, elevated AFP levels may also be seen in sarcomas, yolk sac tumors, and hamartomas. All children being evaluated for HCC should be tested for exposure to hepatitis B and C viruses.

Abdominal ultrasonography is obtained as an initial imaging study. Doppler ultrasound can also detect the presence of tumor extension into or thrombosis of major vessels, namely, the hepatic veins, IVC, and portal vein. A CT scan is essential in assessing the relationship of the tumor to adjacent vital structures, such as bile ducts and vessels, and excluding intraabdominal tumor extension beyond the liver. MRI can similarly be used in this setting but does not necessarily provide significant advantages over CT. Because hepatoblastoma frequently spreads hematologically to the lungs, chest CT should also be performed. Bone scintigraphy is recommended for staging in children with HCC because of the high incidence of bone metastases. Hepatoblastoma characteristically appears as a unifocal mass surrounded by a pseudocapsule; it may be a pure epithelial type that contains fetal or embryonal cells or a mixture of the two histologic subtypes, which contains mesenchymal tissue in addition to epithelial components. On the other hand, HCC is characterized by large, pleomorphic epithelial cells that appear much like mature hepatocytes. In gross appearance, HCC forms multifocal nodules that lack a fibrous tumor and often lead to diffuse intrahepatic involvement. Unlike in adults, there has been no indisputable evidence that histopathologic type has any bearing on prognosis.

A standard TNM system has been used for staging purposes, but much effort has been put into the development of a pretreatment staging system, known as the PRE-Treatment EXTent of disease (PRETEXT) definition system (Table 117.4). The PRETEXT system was developed by the International Childhood Liver Tumor Strategy Group (SIOPEL) for staging and risk stratification of liver tumors.[39] It divides the liver into four sections based on segmental anatomy of the liver, and the tumor is subsequently classified by the number of tumor-free sections of liver (Fig. 117.23). This system takes caudate lobe involvement, tumor rupture, ascites, extension into the stomach or diaphragm, tumor focality, lymph node involvement, presence of distant metastases, and vascular involvement into further consideration. PRETEXT staging defines for the surgeon, when upfront resection, prior to chemotherapy is possible (PRETEXT 1 or II) Patients are considered at high risk if they have a serum AFP level above 100 ng/mL, extension beyond the liver, distant metastases, intraperitoneal hemorrhage, and invasion of the hepatic veins, IVC, or portal vein. For PRETEXT I and II, hepatoblastoma may be resected by segmentectomy or anatomic lobectomy prior to chemotherapy.

Liver transplantation is a potential surgical option for patients with a massive unresectable tumor. Neoadjuvant chemotherapy is used for tumor shrinkage and potential complete resection. Interestingly, some advocate the use of preoperative chemotherapy to treat what would otherwise be residual microscopic disease left

TABLE 117.4 **PRETEXT Definition for Hepatoblastoma**

PRETEXT GROUP	DEFINITION
I	One section involved; three adjoining sections are tumor free
II	One or two sections involved; two adjoining sections are tumor free
III	Two or three sections involved; one adjoining section is tumor free
IV	Four sections involved

PRETEXT, PRE-Treatment EXTent of disease.

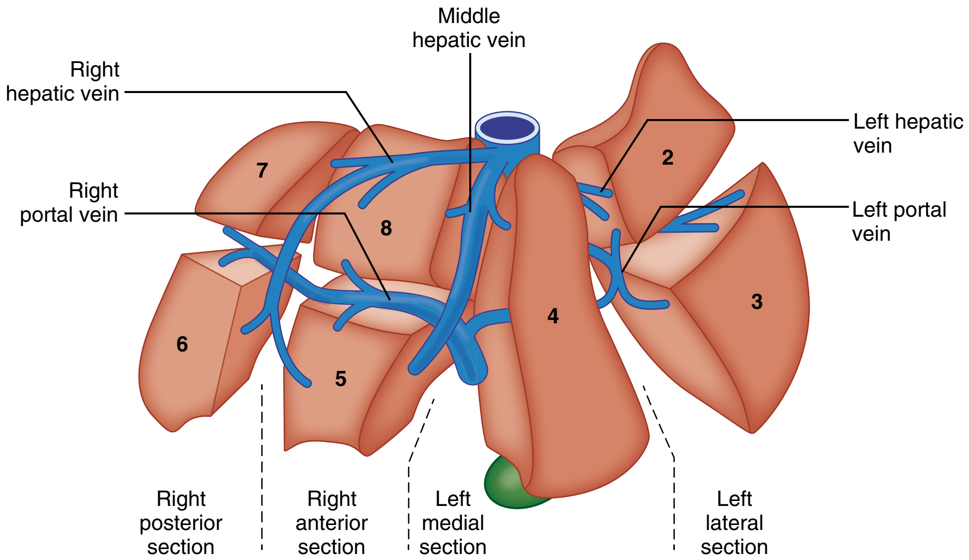

FIGURE 117.23 A diagram of the PRETEXT definition system for hepatoblastoma. The liver is divided into four sections based on segmental anatomy of the liver, and the tumor is subsequently classified by the number of tumor-free sections of liver. (From Roebuck DJ, Aronson D, Clapuyt P, et al. 2005 PRETEXT: A revised staging system for primary malignant liver tumors of childhood developed by the SIOPEL group. *Pediatr Radiol.* 2007;37:123-132.)

behind after resection. It could eradicate tumor cells that could respond to hepatotrophic factors during liver regeneration, thereby decreasing the risk of recurrence. There are two current approaches to hepatoblastoma: (1) tumor resection followed by chemotherapy and (2) tumor biopsy followed by chemotherapy and delayed resection. Patients with stage I tumors with pure fetal histology usually do not require postoperative chemotherapy. However, patients with stage II or higher tumors and tumors of any other type of histology do require chemotherapy consisting of cisplatin, 5-fluorouracil, and vincristine. For patients with residual tumor after resection, chemotherapy should be coupled with an evaluation for transplantation. Criteria for transplantation include having no more than three tumors smaller than 3 cm in diameter and no evidence of extrahepatic disease or vascular invasion. With relapses, doxorubicin, irinotecan, and ifosfamide are used with moderate success. Another modality being used with variable success in children whose tumors are unresponsive to systemic chemotherapy is direct arterial chemotherapy or chemoembolization. Long-term outcomes have yet to be determined. Long-term disease-free survival of more than 85% to 90% can be achieved for resectable hepatoblastoma, although similar estimates have been noted for patients with unresectable hepatoblastoma treated by liver transplantation. The same cannot be said for HCC, in which survival rates with partial hepatectomy remain poor because of relapse. In the past decade, early transplantation has been shown to result in better outcomes in some centers and should be considered when tumors are unresectable despite chemotherapy.

Teratoma

Teratomas are typically benign neoplasms that contain elements derived from more than one of the three embryonic germ layers (endoderm, mesoderm, and ectoderm). They are composed of tissue that is foreign to the anatomic site in which they are found. Although teratomas may occur anywhere along the midline, they are usually found in sacrococcygeal, mediastinal, retroperitoneal, and gonadal locations. Teratomas may be solid, cystic, or mixed and are classified as mature or immature. Although immature teratomas can be potentially malignant, the incidence of malignant transformation in mature teratomas is low. There is a preponderance based on gender; almost 80% of all teratomas occur in females. Moreover, location has been associated with age, as evidenced by the fact that extragonadal tumors occur primarily in neonates and young children, whereas gonadal tumors are more commonly noted in adolescents.

Sacrococcygeal teratomas (SCTs) account for 60% of all teratomas and can be manifested as large exophytic masses in utero. In such cases, they are detected on prenatal ultrasound. Complications include polyhydramnios and fetal hydrops, which can result in fetal demise caused by a tumor-induced vascular steal syndrome that leads to high-output heart failure. Symptoms can include weakness, paralysis, bowel or bladder dysfunction, and other neurologic symptoms that may indicate intradural spinal extension. The diagnosis can be made clinically, especially with exophytic SCTs. If the AFP or β-hCG level is elevated, yolk sac or choriocarcinoma components, respectively, make up the teratoma. CT and MRI can help to delineate intraabdominal lesions or to determine the extent of the pelvic or abdominal component.

Surgical resection is the standard of care and should be performed promptly because of the risk of hemorrhage and tumor rupture. Operative planning must consider the degree of intraabdominal extension (Fig. 117.24). Most tumors can be resected by a posterior approach, in which a chevron incision allows the division of the gluteal muscles, ligation of the blood supply, and en bloc resection of the tumor and coccyx. It is important to preserve the anorectal complex to maintain long-term continence. External tumors with significant intraabdominal extension require a combined abdominal and posterior approach, whereas teratomas that are entirely intraabdominal may be approached through laparotomy or laparoscopy. Outcomes are favorable with respect to survival and quality of life. The age at diagnosis is the most important factor; those diagnosed at less than 30 weeks of gestation or after 2 months postnatally have a poor prognosis. The risk of malignant transformation associated with embryonal histology is 15% to 20%. Risk of local recurrence ranges from 4% to 11%, although failure to resect the coccyx is associated with a 37% risk of recurrence. AFP levels should be monitored at 3-month intervals for 3 to 4 years. For recurrence, reexcision should be considered.

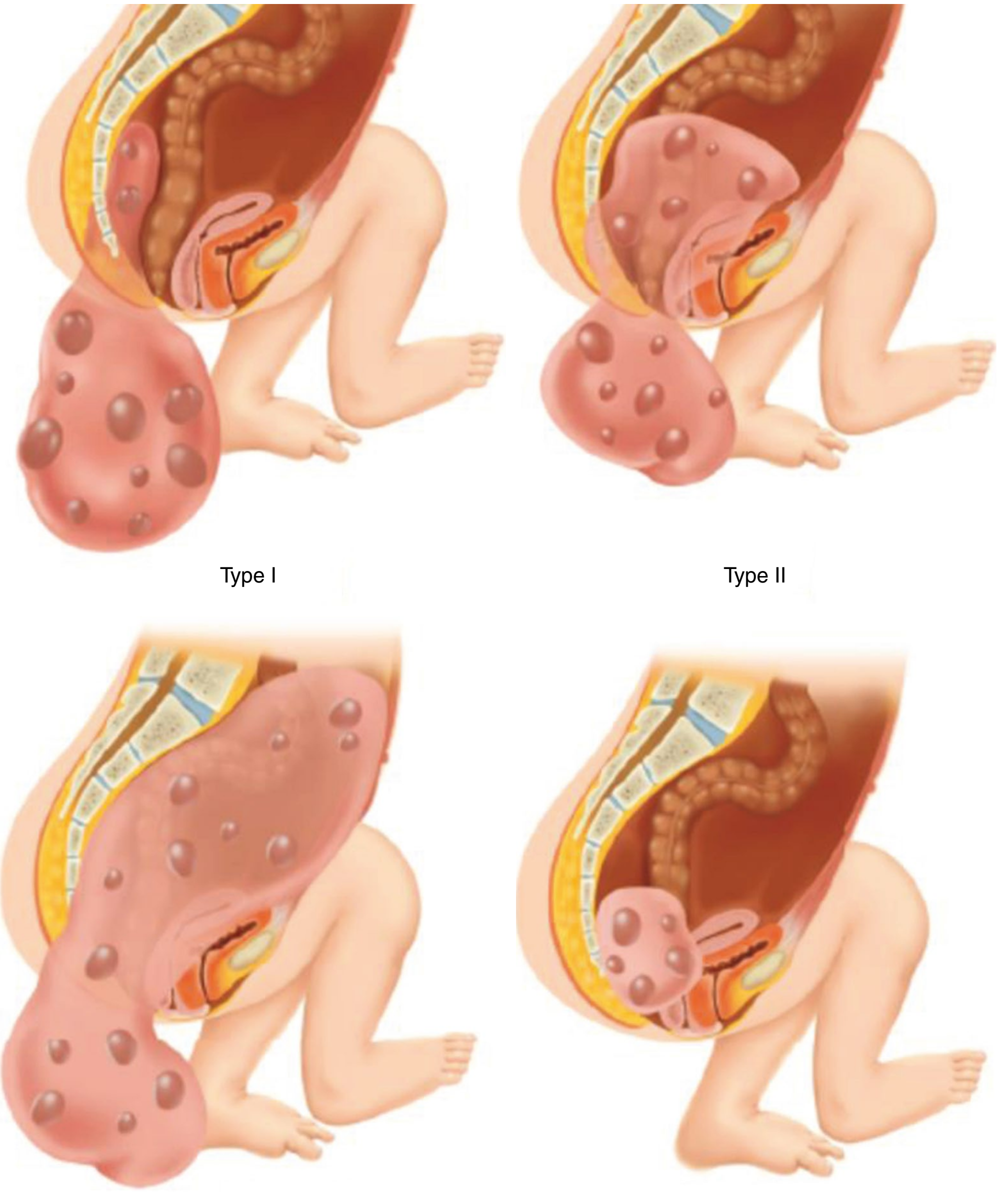
Ovarian Tumor

Approximately 50% of all ovarian lesions in children are neoplastic but are rarely malignant. It is estimated that ovarian malignant neoplasms represent 10% of all ovarian masses but only 1% of childhood cancers. Primary ovarian malignant neoplasms can be classified as germ cell, epithelial cell, and sex cord stromal tumors. Germ cell tumors include teratomas and choriocarcinoma; sex cord stromal tumors consist of granulosa (thecal) and Sertoli (Leydig) cells. Epithelial cell tumors encompass serous and mucinous cystadenomas and cystadenocarcinomas.[40] Symptoms are usually pain related to mass effect. The presence of ascites, omental masses, peritoneal or diaphragmatic implants, adherence to surrounding organs, aortoiliac adenopathy, size larger than 8 cm, or contralateral ovarian mass should raise suspicion for malignancy.

Teratoma is the most common ovarian germ cell tumor. It also represents the most common pediatric ovarian neoplasm and accounts for 25% of all childhood teratomas. These tumors occur with equal frequency in either ovary or may even be bilateral in 10% of patients. They typically are manifested with abdominal or pelvic pain and may involve ovarian torsion in approximately 25% of patients. Germ cell tumors account for 7% to 80% of all neoplastic ovarian masses. Dysgerminomas are the least differentiated of the germ cell tumors and are bilateral in 10% to 15% of cases. Although pure dysgerminomas are malignant, they tend to present while still localized and are highly responsive to chemoradiation. Survival is almost 90% with complete surgical resection.

Sex cord tumors arise from the stromal elements of the ovary, producing hormones that may result in precocious puberty. Interestingly, these tumors have been associated with Peutz-Jeghers syndrome. Abnormal menstruation, swelling, and pain are common chief complaints. Outcomes after resection are good in this group because most lesions are still limited to the ovary. Advanced-stage tumors are responsive to platinum-based chemotherapy. Granulosa cell tumors account for 1% to 10% of ovarian malignant neoplasms in females younger than 20 years, whereas Sertoli-Leydig cell tumors account for 20% of ovarian sex cord stromal tumors. Because they are androgenic, serum testosterone metabolite levels can be elevated. With estrogen excess, patients develop early sexual characteristics, such as breast or labial enlargement, axillary and pubic hair growth, and galactorrhea.

Epithelial tumors occur in less than 20% of all ovarian tumors in the pediatric patient population. The two main histologic subtypes are serous and mucinous tumors, which can be further described as benign, malignant, or borderline malignant. It is possible to classify the subtypes as adenoma or



Type I

Type II

Type III

Type IV

FIGURE 117.24 Sacrococcygeal teratoma Altman classification types I to IV. Type I is resected entirely from perineal approach. Types II and III require combination of perineal and abdominopelvic approach. Type IV is resected entirely via abdominal approach.

adenocarcinoma; adenocarcinoma is extremely rare with a poor prognosis. Tumor biomarkers, AFP and β-hCG, help provide information about tumor biology and can be used to measure treatment response. If there is any evidence of menstrual abnormalities or precocious puberty, luteinizing hormone and follicle-stimulating hormone levels should also be checked. Ultrasound examination can evaluate the tumor and contralateral ovary. A cross-sectional image study can provide information on tumor extension, regional adenopathy, and distant metastasis.

Surgery is the mainstay of therapy and aims to ensure complete resection, with preservation of reproductive function when possible. An ovarian-sparing approach is recommended when a simple cystic mass or benign teratoma is suspected. Definitive treatment for malignancy is oophorectomy or salpingo-oophorectomy. Care should be taken to resect the tumor without disrupting the capsule or spilling tumor contents to avoid upstaging of malignant lesions. Ascites, if present, should be tested for cytology evidence of tumor. At operation, liver, diaphragm and peritoneal surfaces, and omentum are examined for ovarian implants, which, when present, should be biopsied for staging and treatment purposes. Bilateral retroperitoneal, iliac, paraaortic, and perirenal lymph nodes should be sampled for appropriate staging. Ascites or peritoneal washings should be sent for cytology. Chemotherapy is indicated for any ovarian tumor with extension beyond the affected ovary, which is often the case with germ cell and epithelial cell tumors. A combination of low-dose bleomycin, etoposide, and cisplatin treatment in patients with stage II disease has resulted in event-free and overall survival rates of 87.5% and 93.8%, respectively.

PEDIATRIC CRITICAL CARE: EXTRACORPOREAL LIFE SUPPORT

Extracorporeal life support (ECLS), often referred to as ECMO is a cardiopulmonary bypass delivering temporary life support for the critically ill child with acute respiratory and/or cardiac failure. ECLS achieves sufficient gas exchange, with carbon dioxide removal and oxygenation of blood to maintain stable circulatory support. Since its first reported neonatal experience in 1976, ECLS has not only become a standard therapeutic option for cardiopulmonary failure that is refractory to maximal medical therapy but has also become widely used for a variety of clinical applications, such as extracorporeal cardiopulmonary resuscitation (ECPR) and severe sepsis. Although the exact efficacy of ECPR in neonatal and pediatric resuscitation remains controversial and yet to be determined, the use of ECPR has become a common practice in many hospitals around the globe.

The major indications for neonatal ECMO include meconium aspiration, respiratory distress syndrome, PPHN, sepsis, and CDH. Meconium aspiration is the most common application for neonatal ECMO with the highest survival rate (>90%). Indications for neonatal ECMO vary among institutions. In general, ECMO is indicated when an infant's overall cardiopulmonary function deteriorates to a point of ~80% predicted mortality. Two guidelines have been used as predictors for survival without ECMO: the alveolar-arterial difference in the partial pressure of oxygen ($PAO_2 - PaO_2$ [also known as $AaDO_2$]) and the oxygen index (OI). $AaDO_2$ greater than 610 for longer than 8 to 12 hours and $AaDO_2$ greater than 620 for 6 hours, associated with extensive barotrauma and severe hypotension requiring inotropic support, are indications for ECMO. The OI is calculated as the fraction of inspired oxygen (usually 1.0) × mean airway pressure × 100 divided by PaO_2. An 80% mortality is observed with an OI greater than 40. Prediction tools can be used to estimate probability of survival.[41]

Contraindications to neonatal ECMO are severe prematurity due to a high risk of intracranial bleeding, weight less than 2 kg, presence of an intracranial bleed, and a nonreversible pulmonary disease such as congenital alveolar dysplasia. Additional exclusion criteria include the presence of cyanotic congenital heart disease or major genetic defects that preclude survival and intractable coagulopathy.

Older children with severe respiratory failure refractory to medical management resulting from pneumonia, acute respiratory distress syndrome, asthma, burn inhalation injury, cardiac failure resulting from primary cardiac dysfunction or following cardiac surgery, or severe sepsis may improve with ECMO. For respiratory failure, ECMO allows for "lung rest" and decreases barotrauma from high ventilator settings and hemodynamic support as the underlying infection is treated.

The right internal jugular vein and common carotid artery are used for venoarterial (VA) cannulations because of vessel sizes in young children to accommodate cannulas and collateral circulation. The carotid artery is usually ligated when the canula is removed, as repair is prone to thrombosis. Carotid ligation is generally very well tolerated in babies. In older children, to avoid carotid ligation, the femoral artery is often used; however, distal flow to the leg can be occluded by large canula size, and a retrograde flow canula should be inserted that is connected to the circuit to keep the leg perfused.

The ECMO circuit is composed of a silicone rubber bladder that collapses when venous return is diminished, roller pump, membrane oxygenator, heat exchanger, tubing, and connectors. The basic principle of ECMO is that desaturated mixed venous blood from the right atrium drains through the venous cannula to the bladder and is pumped to the membrane oxygenator, where carbon dioxide is removed, and oxygen is added. The oxygenated blood then passes through the heat exchanger and is returned to the patient through the arterial cannula. Systemic anticoagulation to prevent clotting of the ECMO circuit puts patients at risk for bleeding complications. Indicators of lung recovery include an increasing PaO_2, improved lung compliance, and clearing of the chest radiograph. As the pulmonary function recovers, the patient is trialed off bypass by clamping the cannulas. If tolerated, the patient is taken off ECMO on moderate conventional ventilatory settings. Venovenous (VV) bypass uses a double-lumen single cannula. VV ECMO works well for respiratory failure but requires good cardiac function. Often, perfusion of well-oxygenated blood through VV ECMO restores hemodynamic stability. In older pediatric and adult patients, venous cannulas can be placed via both the internal jugular and femoral veins to achieve VV ECMO circulation. Bleeding is the most common complication of ECLS, and it can occur anywhere from catheter sites and surgical sites such as the thoracic cavity to intracranial bleeds. Gestational age is the most significant predictor of intracranial hemorrhage on ECLS, and premature infants less than 34 weeks of gestational age are at highest risk. Other complications include seizures; neurologic impairment; renal failure requiring hemofiltration or hemodialysis; hypertension; infection; and mechanical malfunction of membrane oxygenator, pump, and heat exchanger as well as the cannulas themselves.

Ethics in Maternal-Fetal Surgery
Conclusion

INTRODUCTION

Maternal-fetal surgery represents therapeutic interventions to treat prenatally diagnosed anomalies, a concept held in great controversy as recently as the past 50 years. Despite the complex ethical milieu, dedicated pioneers of the field persisted with multidisciplinary collaboration, rigorous large animal modeling, and advances in surgical technique. This groundbreaking work has led to maternal-fetal surgery becoming the standard of care for treating certain fetal anomalies, such as myelomeningocele (MMC) and advanced twin-twin transfusion syndrome (TTTS).[1]

HISTORY OF MATERNAL-FETAL SURGERY

As early as the 1960s, limited intrauterine procedures had developed, including fetal blood transfusion and amniocentesis. The first open fetal surgical intervention was performed in 1981 by Dr. Michael Harrison at the University of California, San Francisco (UCSF), in a fetus with obstructive uropathy.[2] The successful placement of a fetal vesicoamniotic shunt proved that an operation in a pregnant female could be successful, safe, and maintain pregnancy. With advances in surgical technique, maternal-fetal surgery now takes many forms, including open intervention via hysterotomy, minimally invasive fetoscopy, and percutaneous fetal access using ultrasound (US) guidance.

The initial rationale behind the birth of maternal-fetal surgery derived from the idea that certain anatomic defects in utero could lead to disastrous postnatal consequences. In theory, correction of the anatomic defect would lead to a normalization of physiology after birth. As always, things are more complex than they seem. "Simple" anatomic repairs were more complicated in practice, with fetal access and uterine closure remaining a crucial obstacle. In addition to the complex pathophysiology and surgical techniques, all maternal-fetal surgical interventions demand careful consideration of two patients, the fetus and the pregnant female. At first, maternal-fetal interventions were indicated only in uniformly lethal conditions because it was deemed a justifiable risk for the pregnant patient. As fetal access improved and minimally invasive techniques developed, indications broadened (Box 118.1). Maternal-fetal surgery's success is largely due to the advent of US, offering a noninvasive method to observe fetal development. Prenatal US helped determine findings indicative of serious disorders that could be amenable to intervention.

Anesthesia and Perioperative Care

Maternal-fetal surgery, by definition, involves two patients undergoing surgery simultaneously—the pregnant female and the fetus. For each, there are important perioperative considerations that must be understood. Maternal-fetal anesthesia must take into consideration normal maternal and fetal physiology, the pathology leading to the operation, the surgical technique, and how these all interact to affect the health of both the pregnant patient and the fetus.[3]

Most maternal-fetal procedures are performed either in the latter part of the second trimester or early third trimester. To provide safe anesthesia care to the pregnant patient, it is essential to know the physiologic changes that occur during pregnancy. These changes include a marked increase in cardiac output coupled with a decrease in systemic vascular resistance, increased minute ventilation and oxygen consumption with decreased functional residual capacity, increased incidence of gastroesophageal reflux and aspiration, physiologic anemia as a result of dilution, and increased renal blood flow and glomerular filtration rate. In addition, pregnant patients undergo significant anatomic changes, including weight gain, an enlarging gravid uterus, increasing vascularity of the mucous membranes, and soft tissue edema, which lead to challenges in airway management and the potential for aortocaval compression in the supine position.

BOX 118.1 Conditions Amenable for Maternal-Fetal Interventions

- Myelomeningocele (MMC)
- Twin-twin transfusion syndrome (TTTS)
- Twin reversed arterial perfusion (TRAP) sequence
- Congenital diaphragmatic hernia (CDH)
- Tumors causing hydrops:
  - Sacrococcygeal teratoma (SCT)
  - Congenital pulmonary airway malformation (CPAM)
  - Cervical teratoma
- Airway obstruction/congenital high airway obstruction syndrome (CHAOS)
- Amniotic band syndrome
- Urinary tract obstruction
- Renal agenesis
- Congenital heart disease
- Fetal anemia

Many in utero procedures, including fetoscopic laser for TTTS, radiofrequency ablation (RFA), fetal transfusion, insertion of bladder or thoracic shunts, and fetoscopic endoluminal tracheal occlusion (FETO), may be successfully performed under local anesthesia. However, other procedures, such as open MMC repair and ex utero intrapartum treatment (EXIT) procedures, most often require general anesthesia for both the pregnant patient and the fetus. For these procedures, the prevention of preterm labor is essential. Thus, tocolytic agents are administered before, during, and after surgery, depending on the risk of preterm labor. In addition, volatile agents such as sevoflurane are used to maintain uterine relaxation and titrated accordingly based on uterine tone as assessed by the surgeon. It is important to provide fetal anesthesia and analgesia during all potentially stimulating fetal interventions. This can be achieved either by placental transfer of agents or by direct fetal administration, either intramuscularly or via the umbilical vessels. In addition to preventing fetal movement, fetal anesthesia has been shown to blunt stress responses to noxious stimuli.[4] Intraoperative fetal monitoring is essential and is most often performed either via intermittent or continuous fetal echocardiography. For patients requiring a laparotomy or cesarean section, adequate postoperative pain control is usually achieved with either an epidural catheter or bilateral quadratus lumborum blocks. After surgery, it is important to perform close monitoring of the fetal heart rate and uterine activity for at least 24 to 48 hours after open maternal-fetal surgery as well as after any fetoscopic procedures that portend significant risk of fetal complications in the early postoperative period.

There are significant risks to both the pregnant patient and the fetus during maternal-fetal surgery. Maternal risks for all maternal-fetal operations include bleeding, pulmonary edema, chorioamnionitis, premature rupture of membranes (PROM), preterm labor, and premature delivery.[5] Because of the hysterotomy, a female undergoing open maternal-fetal surgery is at increased risk of uterine dehiscence and uterine rupture for not only the current pregnancy but also all future pregnancies.[6] A registry review by the North American Fetal Therapy Network (NAFTNet) demonstrated a 9.6% uterine rupture rate in a subsequent pregnancy after prior open MMC repair.[7] Because of this risk, pregnant females undergoing open maternal-fetal surgery are not allowed to labor in current or future pregnancies and thus must undergo cesarean sections for all deliveries.

To reduce maternal and fetal morbidity, alternative surgical approaches to fetal MMC repair were developed, including laparotomy-assisted fetoscopic and percutaneous fetoscopic MMC repair. In comparison to open repair, fetoscopic MMC repair had a higher rate of PROM and dehiscence and leakage from the MMC repair site but a remarkably lower rate of uterine dehiscence (0% vs. 11%).[8] For this reason, pregnant patients undergoing fetoscopic procedures are usually allowed to labor and deliver vaginally in their current and subsequent pregnancies.

Overall, the Achilles' heel for maternal-fetal surgery was and remains the control and prevention of preterm labor. Until the issue of preterm birth after maternal-fetal surgery is solved, the potential addition of prematurity to the underlying diagnosis of the fetus must be weighed against any potential benefit of prenatal intervention.

MATERNAL-FETAL SURGERY BY ANOMALY

This is not an exhaustive list of all possible fetal anomalies amenable to maternal-fetal intervention but a review of the current state of maternal-fetal surgery organized by the major anomalies.

Myelomeningocele

In the United States, approximately four children are born daily with MMC, making it one of the most common congenital defects resulting in significant lifelong morbidity. In MMC, the incomplete closure of the neural tube during early embryonic development results in exposed neural tissue and leakage of cerebrospinal fluid (CSF). These patients display a wide range of lifelong clinical consequences that affect multiple organ systems. Many children experience lifelong paralysis and bowel and bladder incontinence, depending on spinal level affected, as well as musculoskeletal deformities and cerebral anomalies.[9] The immediate postnatal consequence of incomplete neural tube closure is hindbrain herniation (Arnold-Chiari II malformation) and resulting hydrocephalus. Before the advent of ventriculoperitoneal (VP) shunting, hydrocephalus was the main cause of mortality. VP shunting is not without consequence, carrying the risk of infection and shunt malfunction, often necessitating multiple operative revisions. Chiari II malformation, hydrocephalus, and other cerebral anomalies, including hypoplastic pons, abnormal corpus collosum, and stenogyria, may be associated with lower cognitive function.[10,11]

Rationale for Prenatal Surgery

The neurologic deficits associated with MMC are attributed to a "two-hit hypothesis" of injury. The first "hit" is anomalous neural placode leaving an open spinal cord, caused by a complex array of genetic and environmental factors. CSF leaks from the spinal defect, resulting in hindbrain herniation, obstruction of CSF flow, and ultimately, hydrocephalus. The second "hit" relates to subsequent spinal cord exposure to the mechanical trauma of the uterine wall and the toxicity of amniotic fluid.[12] Worsening neurologic function over time has been demonstrated in fetuses with MMC. Ideally, the first hit would be prevented. Folic acid is known to prevent neural tube defects and is routinely administered in prenatal vitamins during pregnancy and recommended for females trying to become pregnant. Unfortunately, folic acid supplementation does not eliminate spina bifida, and children continue to be born with this potentially devastating defect. The hope of protecting the spinal cord from secondary trauma inspired surgeons to seek techniques to close the spinal cord defect in utero.

Ovine models of fetal MMC validated the concerns of damaging effects of amniotic fluid exposure.[12] Further experiments in fetal MMC repair demonstrated rescued neurologic function compared with postnatal repairs.[13] Observational studies of preliminary human maternal-fetal interventions at the UCSF, Children's Hospital of Philadelphia, and Vanderbilt University similarly demonstrated improved neurologic outcomes as well as decreased need for VP shunting.[14] These promising findings prompted a multi-institutional prospective randomized trial, the Management of Myelomeningocele Study (MOMS), that compared open fetal repair with postnatal repair.[15]

Open Fetal Repair of Myelomeningocele and the Management of Myelomeningocele Study Trial

Open fetal repair of MMC comprises maternal laparotomy, uterine hysterotomy, and closure of the spinal defect. Repair is typically planned for mid–second trimester, allowing for feasibility of technical repair while mitigating damage done by uterine and amniotic fluid–associated trauma.

In 2003, the UCSF, Children's Hospital of Philadelphia, Vanderbilt University, and George Washington University collaborated with the National Institutes of Health to conduct a randomized controlled study comparing fetal versus postnatal MMC repair. This landmark study, MOMS,[15] randomized patients to open fetal repair of the MMC or repair after delivery based on strict inclusion and exclusion criteria (Table 118.1). Open fetal repair was performed via maternal laparotomy and hysterotomy with primary repair or the use of skin allografts to close the fetal MMC. The trial demonstrated that prenatal closure of the defect let to improved distal neurologic function as well as decreased hindbrain herniation and the need for CSF shunting. Prenatal repair was so much more efficacious than postnatal repair that the safety monitoring committee stopped the planned goal enrollment of 200 patients at 183 patients.

The MOMS trial had two primary outcomes. The first outcome was a composite of fetal or neonatal death or the need for CSF shunt, capturing either placement of shunt or having met the objective criteria for shunt placement. There were no maternal deaths and two perinatal deaths in each group. The occurrence of this composite outcome in the prenatal and postnatal surgery groups at 12 months of age was 68% and 98%, respectively ($P < 0.001$). Although that outcome encompasses all patients who met the predefined criteria for shunt placement, actual shunt placement was 40% in the prenatal group and 82% in the postnatal group ($P < 0.001$). The other primary outcome was a composite score of the Mental Development Index and Bayley Scales of Infant Development Index and the child's motor function, adjusting for spinal level. The MOMS trial reported significant functional and neurologic improvement at 30 months of age in the prenatal surgery group ($P = 0.007$). The prenatal surgery group had numerous other benefits in post hoc analyses, including improved ability to walk without devices or orthotics in the prenatal surgery group (42% vs. 21%, $P = 0.01$) and decreased hindbrain herniation at 12 months in the prenatal surgery group (64% vs. 96%, $P < 0.001$). Additionally, even though the prenatal surgery group had more severe anatomic lesion levels, this group had improved motor function compared with the postnatal surgery group. A secondary analysis of the study population demonstrated that these functional benefits persist through school age.[16]

Significant maternal morbidity was encountered in the prenatal intervention group, including oligohydramnios, chorioamniotic separation, placental abruption, and spontaneous rupture of

TABLE 118.1 **Complete Inclusion and Exclusion Criteria for the Management of Myelomeningocele Study**

INCLUSION CRITERIA

1. Singleton pregnancy
2. MMC lesion between T1 and S1 with hindbrain herniation
3. Normal karyotype
4. Maternal age of 18 or older
5. Gestational age at randomization of 19.0–25.9 weeks

EXCLUSION CRITERIA

1. Nonresident of the United States
2. Insulin-dependent pregestational diabetes
3. Fetal anomaly unrelated to MMC
4. Kyphosis in the fetus of 30 degrees or greater
5. Current or planned cerclage or documented history of incompetent cervix
6. Risk of preterm birth (shortened cervix)
7. Placental abruption or placenta previa
8. BMI ≥35
9. Previous spontaneous delivery before 37 weeks' gestation
10. Maternal-fetal Rh isoimmunization, Kell sensitization, or neonatal alloimmune thrombocytopenia
11. Maternal HIV or hepatitis B status positive
12. Known hepatitis B positivity
13. Uterine anomaly, such as large or multiple fibroids or Müllerian duct abnormality
14. Other maternal medical conditions, which is a contraindication to surgery or general anesthesia
15. Patient does not have a support person
16. Inability to comply with travel and follow-up requirements
17. Patient does not meet other psychosocial criteria to handle the implications of the trial
18. Participation in another intervention study that influences maternal and fetal morbidity and mortality or participation in this trial in a previous pregnancy
19. Maternal hypertension, which would increase the risk of preeclampsia or preterm delivery

BMI, Body mass index; *HIV*, human immunodeficiency virus; *MMC*, myelomeningocele.

membranes. One-third of females had an area of dehiscence or very thin uterine scar at the time of delivery. Those in the prenatal intervention group were born on average 3 weeks early (34.1 vs. 37.3 weeks), and 13% were born before 30 weeks' gestational age.

Fetoscopic Myelomeningocele Repair

Given the significant maternal morbidity associated with open repair, minimally invasive techniques have been pursued, with the goal of sparing the morbidity associated with hysterotomy and preserving the option of vaginal delivery (Fig. 118.1). Although fetoscopic techniques have been rigorously studied and validated via animal model experimentation, there has not been, nor is it likely that there will be, a randomized controlled trial comparing fetoscopic versus open MMC repair.[17] Multiple techniques of uterine access have been described, including both total percutaneous and laparotomy-assisted uterine access.[18] A recent systematic review found that percutaneous fetoscopic repair is associated with higher rates of preterm birth compared with the laparotomy-assisted technique. However, both fetoscopic techniques resulted in higher rates of dehiscence and leakage at MMC repair site compared with the open technique.[19] In a cohort analysis of the first 300 fetoscopic cases from the Fetoscopic Myelomeningocele Repair Consortium, anatomic levels of spinal lesion, mean gestational age, and distribution of motor function in relation to level of the lesion were similar between open and fetoscopic groups. One-third of fetoscopically managed patients were delivered vaginally. Prenatal and postnatal outcomes up to 12 months of age were similar between the fetoscopic and open fetal repairs.[18]

In summary, prenatal repair of MMC contributes to improved outcomes in children, with reduction of hindbrain herniation and enhanced motor outcomes. Spina bifida–related neonatal and infant mortality continues to decline, serving as a testament to increased folate supplementation as well as advances in surgical treatment.[20] The results of the MOMS trial are one of the most important milestones in the clinical success of maternal-fetal surgery because the trial demonstrated efficacy in treating a nonlethal condition. Further research and improved techniques continue to be investigated to minimize the risks to both the fetus and mother as well as to further improve the neurologic outcomes of fetal repair.

Sacrococcygeal Teratoma

Sacrococcygeal teratoma (SCT) is one of the most common congenital tumors, with an estimated incidence of 1:35,000 births. Although long-term outcomes for infants with SCT are generally excellent, SCTs identified prenatally can grow to a tremendous size in relation to the fetus and can cause high-output cardiac failure and nonimmune hydrops through vascular shunting. The mortality rate for SCTs diagnosed prenatally approaches 50%.[21] Additionally, internal or external hemorrhage of SCT can lead to fetal anemia, hypovolemia, and intrauterine fetal demise. Other complications of a large SCT include preterm labor and dystocia, and a traumatic delivery may result in tumor rupture, hemorrhage, and neonatal death.

The fetus with a large SCT has a high risk for mortality, especially when associated with nonimmune fetal hydrops. In this select group of fetuses with SCT, maternal-fetal interventions

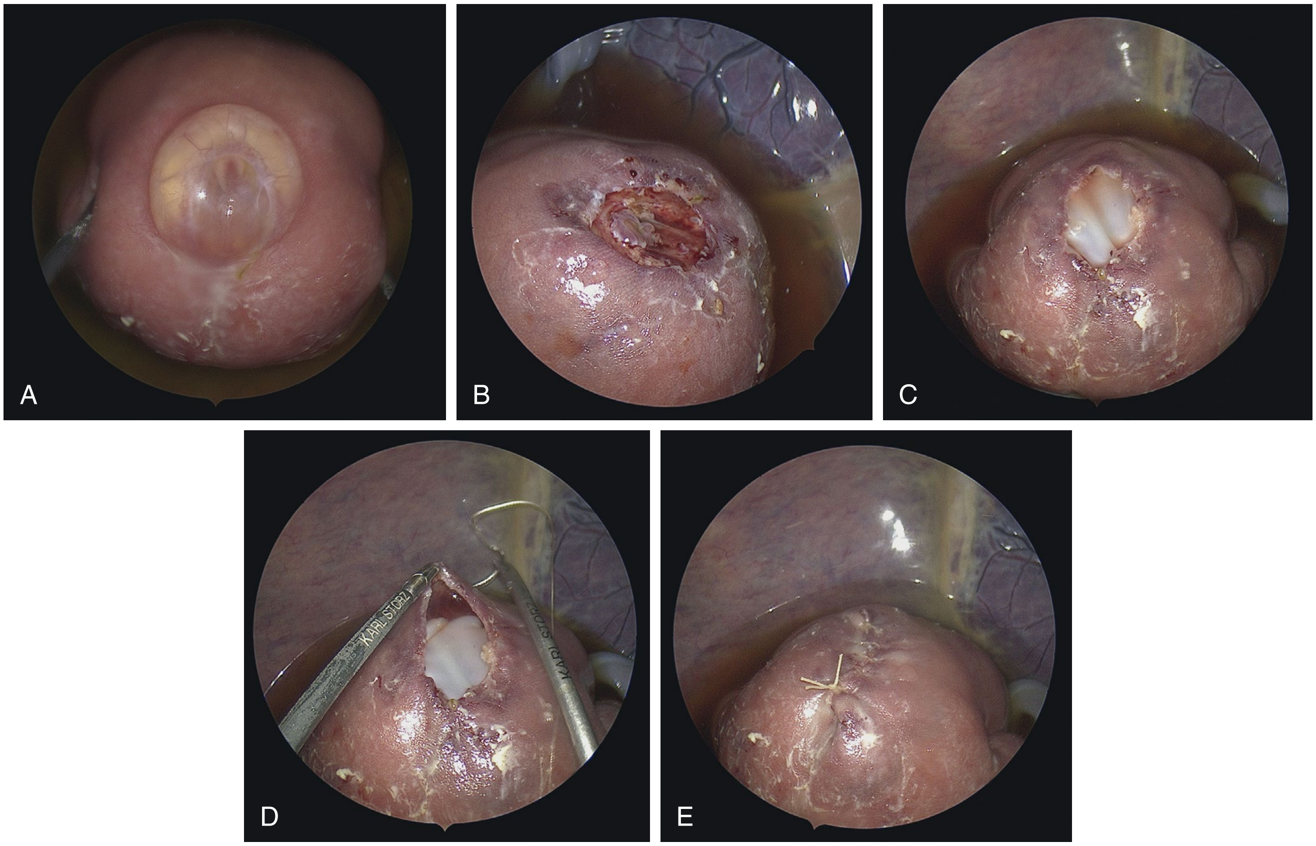

FIGURE 118.1 Intrauterine image of myelomenigicoele ("Cystic" in figure A) in the lower back of a fetus. Laparotomy-assisted fetoscopic myelomeningocele (MMC) closure. (A) MMC. (B) After dissection of the placode. (C) Dural closure with umbilical cord patch. (D) Suturing skin. (E) Primary skin closure. (Courtesy Ca'Rina Gidrey.)

include open fetal resection, RFA, and EXIT-to-resection procedure. Outcomes of maternal-fetal intervention are mixed, with survival ranging from 38% to 75%.[22] Survival in hydropic SCT patients not undergoing maternal-fetal intervention is likely less than 10%. The most common approach for fetal resection of an SCT is a maternal laparotomy and hysterotomy with resection or debulking of the tumor. Open surgical intervention appears superior in regard to decreased interventions, lower failure rates, and survival to discharge.[23] In the setting of purely cystic SCT, intrauterine cyst decompression may prevent dystocia or facilitate cesarean section and is associated with a low risk of complications.[23] Tumor debulking using percutaneous coagulation techniques, such as RFA or laser coagulation, to decrease the vascular shunt are minimally invasive alternatives to open resection and have been successfully reported.

Fetal Cervical Masses

Fetal cervical masses are rare but can lead to tracheal and esophageal compression and obstruction, resulting in polyhydramnios, craniofacial defects, cranial nerve injury, and preterm labor.[24,25] As with SCT, highly vascular lesions can result in high-output heart failure and nonimmune fetal hydrops. These masses are typically diagnosed on prenatal US and include cervical teratoma, lymphatic malformations such as cystic hygroma, and other vascular malformations.[24] Even rarer cases include thymic cysts or congenital neuroblastomas.

After US diagnosis, fetal magnetic resonance imaging (MRI) can better characterize the mass, distinguishing between lymphatic lesions and teratomas.[26] This is an important distinction because the presence of cervical teratoma increases the risk of a complicated airway. Polyhydramnios, in utero neck extension, micrognathia, and neck vessel compression are also associated with the need for invasive airway support at birth.[27] Furthermore, fetal MRI estimated lung volumes can predict pulmonary hypoplasia, and measurement of the tracheoesophageal displacement index (TEDI), defined as the sum of the lateral and ventral displacement in millimeters, can predict complicated airway. In the presence of fetal hydrops before 30 weeks' gestation, open fetal resection may be considered because an obstructing cervical mass poses a significant risk to the fetus, with a nearly 20% risk of intrauterine fetal demise.[25]

Ex Utero Intrapartum Treatment Procedure

The EXIT procedure is used to stabilize the airway immediately before complete delivery of the fetus. During an EXIT-to-airway procedure, the uterus is exposed, and a hysterotomy is performed to deliver the fetus's head and neck. Endotracheal intubation is attempted via direct laryngoscopy. Escalation to bronchoscopy or tracheostomy is necessary if laryngoscopy is not successful. In cases of large cystic lesions, decompression of the cyst may facilitate establishing an airway by relieving any airway compression. If any airway cannot be secured, resection of the mass on utero-placental circulation may be necessary. This modification of the EXIT procedure is termed *EXIT-to-resection*. After resection of the mass and establishment of a secure airway, the infant is delivered, and the umbilical cord is ligated and divided. EXIT is not without risk. In a recent systematic review of 235 reported EXIT cases, fetal and neonatal death occurred in 17% of cases, and although there was no maternal death noted, significant adverse maternal events, such as postpartum hemorrhage, were present in 7% of cases.[28]

It is critical to understand that an EXIT procedure is not a cesarean section. Unlike a cesarean section, deep maternal anesthesia is required during an EXIT procedure to maintain complete uterine relaxation and preserve utero-placental circulation to prevent premature transition to neonatal circulation. In a cesarean section, contraction of the uterus is ideal because it is hemostatic; in an EXIT procedure, uterine contraction is detrimental to the fetus and puts the mother at greater risk for hemorrhage.

Congenital Lung Lesions

A variety of pathologic pulmonary lesions are collectively grouped together as congenital pulmonary airway malformation (CPAM), including both bronchopulmonary sequestration (BPS) and congenital cystic adenomatoid malformations (CCAMs).[29] CCAM is characterized by an overgrowth of bronchioles and cyst formation. Typically, fetuses diagnosed with CCAM have normal development. These patients can be followed with serial US with planned postnatal intervention. However, a small percentage of patients with CCAM will develop hydrops. The most common measurement used to predict hydrops risk is the CCAM volume ratio (CVR). CVR is calculated as the volume of the CCAM as a presumed ellipse divided by head circumference. CVR <1.6 has less than 3% risk of developing hydrops.[30] CCAM is more often associated with nonimmune fetal hydrops than other congenital lung lesions. In hydropic patients, fetal echocardiogram serves as the best indicator of need for intervention.[31] CCAMs can be microcystic or macrocystic. These lesions may undergo rapid growth, most often occurring between 22 and 28 weeks' gestational age. During this time, pregnant patients are monitored via weekly US examinations. Microcystic CCAM growth usually plateaus after 28 weeks' gestation, and interval US examinations can be spread out in an otherwise healthy pregnancy. Macrocystic CCAMs differ in that they can enlarge abruptly as a result of fluid accumulation and must be followed closely throughout the pregnancy.[32]

In the setting of hydrops, large, symptomatic macrocystic lesions may be amenable to minimally invasive drainage. Both US-guided cyst aspiration and thoracoamniotic shunt placement have been successfully used in the management of congenital lung lesions. Cyst aspiration can rapidly reduce the volume of the lesion, but fluid reaccumulation is common, necessitating possible reintervention. The use of a thoracoamniotic shunt can reverse hydrops in patients with macrocystic disease (Fig. 118.2).[33] Unfortunately, shunt dislodgement after placement is common, and repeat procedures may be needed in the setting of ongoing fetal distress.

Open maternal-fetal surgery may be offered for the previable fetus with microcystic or solid CCAM.[34] In patients older than 30 weeks' gestation, EXIT or EXIT-to-resection may provide a more stable transition from fetal to postnatal life. It is important to note that after delivery with the administration of positive pressure ventilation, a congenital lung mass may increase rapidly in size, leading to worsening cardiac compression and cardiovascular collapse. Additionally, percutaneous sclerotherapy is another potential fetal therapy in which 5% ethanolamine oleate is injected into the lesion.[35] In this small series by Chon et al., intrauterine fetal demise occurred in 50% of patients. Limited data exist, and further studies are needed to determine efficacy and safety.

Although maternal steroids were initially administered to promote fetal lung maturity in preparation for surgery, preoperative US found resolution of hydrops with survival of fetuses to delivery after maternal administration of steroids, a finding that was confirmed in multiple later series.[34] Steroids appear to be more effective for microcystic than macrocystic lesions. Today, it is common practice to administer maternal steroids for any fetus with a CVR >1.6.

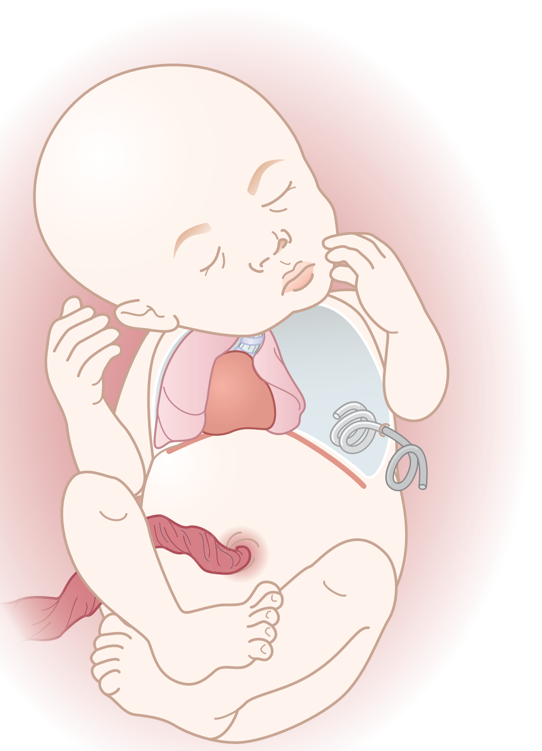

FIGURE 118.2 Thoracoamniotic shunt.

Other techniques have been explored for BPS. Fetal laser ablation of feeding artery may help resolve hydrops. Similarly, feeding artery ablation may help in large hybrid lesions with hydrops or effusions.[36]

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a relatively common congenital lesion with an estimated survival of about 70% to 80%.[37] CDH is often diagnosed prenatally by the hallmark diaphragmatic defect, leading to pulmonary hypoplasia and persistent pulmonary hypertension. Prenatal diagnosis is associated with worse survival because defects must be larger to be seen on fetal imaging.[38] Fetal pulmonary hypoplasia serves as the best predictor of morbidity and mortality. To assess severity in utero, multiple prenatal prediction tools have been developed. Lung-to-head ratio (LHR) is calculated by the ratio of the contralateral lung-to-head circumference, estimating likelihood of pulmonary hypoplasia and thus survival. LHR <1 is associated with poor prognosis, whereas >1.4 suggests almost 100% survival.[38] Using reference LHR values from normal fetuses, the observed-to-expected LHR (O/E LHR) was developed, with less than 20% survival when O/E LHR is less than 25%.[39] Unlike MMC and SCT, which are most often isolated defects, CDH can be associated with other anomalies, including congenital heart disease and chromosomal abnormalities. These associations contribute to the high mortality of this disease.

Early animal models of CDH were developed either by creating a diaphragmatic defect or direct fetal lung compression. In these models, in utero correction of lung compression led to sufficient lung development, serving as a foundation for investigating fetal CDH repair in humans. The first report of fetal diaphragmatic hernia repair was in 1990, creating an abdominal silo to accommodate the reduced viscera after defect repair.[40] Further studies evaluating open maternal-fetal surgery garnered mixed results.[41] It stood to reason that fetuses with the most severe defects would benefit the most from prenatal intervention. After the first successful repair, a prospective trial was executed, comparing fetal and postnatal repair in severe cases of prenatally diagnosed CDH. Yet no difference was found between the two groups in either survival or need for extracorporeal membranous oxygen (ECMO).[41] Interestingly, fetal tracheal occlusion had been associated with lung growth. The fetus normally expels lung parenchymal fluid in utero, but tracheal occlusion could lead to accumulated fluid, resulting in lung growth.

Tracheal occlusion via hysterotomy and placement of metallic clip proved challenging, increasing the risk of preterm labor and prematurity as well as causing tracheal stenosis and a compromised airway on delivery.[42] Survival rate was only 15%. Advances in fetoscopy allowed for fetoscopic balloon placement for tracheal occlusion (Fig. 118.3).[43] After promising results in animal models, a prospective randomized trial of fetal tracheal occlusion for severe left-sided CDH (liver up and LHR <1.4) was initiated in the United States and published in 2003, but no survival benefit was found.[44] These conclusions were challenged in observational studies, leading to the international randomized Tracheal Occlusion to Accelerate Lung Growth (TOTAL) trials. The TOTAL trials were randomized controlled trials evaluating FETO in the setting of left-sided CDH for both moderate (O/E LHR 25%–34.9% or 35%–34.9% with liver herniation) and severe CDH (O/E LHR <25%). In the severe TOTAL trial, the study was stopped early for efficacy, with 40% of the FETO group surviving to discharge compared with 15% in the expectant care group. This benefit was sustained at 6 months of age.[45] The moderate FETO trial did not show benefit of FETO performed at 30 to

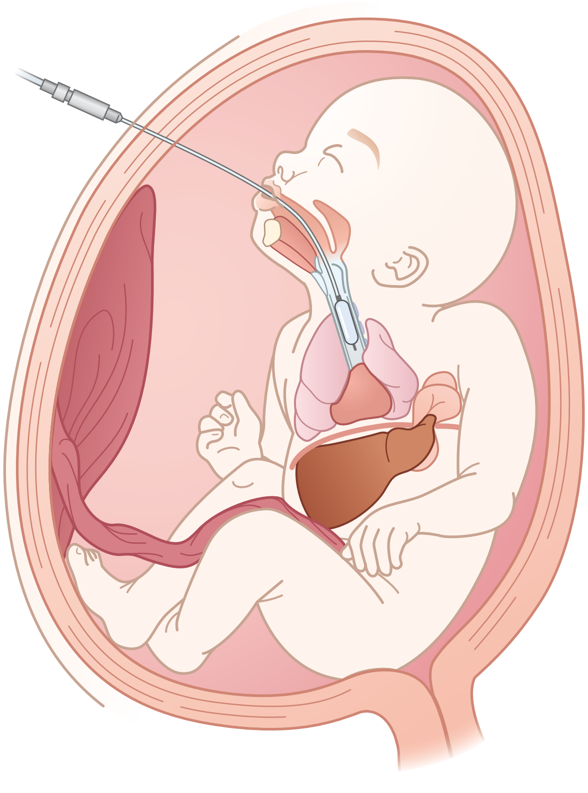

FIGURE 118.3 Tracheal balloon.

32 weeks over expectant management for survival to discharge or need for oxygenation at 6 months.[46]

Based on the results of these trials, FETO is now offered at several fetal centers in the United States to patients diagnosed with severe CDH.[45,46] The procedure is typically performed between 27 and 29 weeks' gestational age. After paralytic, atropine, and sedation are administered intramuscularly to the fetus, a 10-Fr cannula is inserted under US guidance. A fetoscope loaded with a detachable inflatable latex balloon is inserted into the trachea between the cords and carina (Figs. 118.4 and 118.5). The balloon is typically retrieved fetoscopically or punctured percutaneously at 34 weeks' gestational age. However, if unsuccessful, the balloon may need to be removed via an EXIT procedure at delivery to ensure airway patency at birth. Intervention is not without risk; FETO was associated with an increased risk of preterm labor, PROM, and preterm birth.

Twin-Twin Transfusion Syndrome

TTTS is a potentially fatal complication of monochorionic twin pregnancies. In this situation, two fetuses share one placenta, but they are physically isolated in different amniotic sacs. Because of this placental sharing, the twins are at risk for unequal vascular use of the placenta. Although all monochorionic twin pregnancies are at risk, only 10% ultimately will develop TTTS.[1] Overall, this comprises approximately 1 in 50 twin pregnancies in the United States.[47] TTTS is by far the leading indication for operative maternal-fetal intervention.

The pathophysiology of TTTS is related to vascular anastomoses across the placenta. Most monochorionic twins share blood flow via arteriovenous connections. Usually, this intertwin transfusion is net balanced. In TTTS, the transfusion becomes unbalanced, with one twin ("the donor") donating vascular flow to a receiving twin ("the recipient"). The result can lead to oligohydramnios in the donor and polyhydramnios in the recipient, a hallmark of the disease and requisite finding for diagnosis. More devastatingly, this can lead to discordant growth, cardiac failure, hydrops, and death of one or both twins. TTTS is categorized into five stages of severity based on US findings. Stage I is defined by a maximum vertical pocket of amniotic fluid of <2 cm in the donor sac and >8 cm in the recipient sac. Stage II is defined by nonvisualization of donor fetal bladder. Stage III is defined as absent or reversed umbilical artery diastolic flow, reversed ductus venous a-wave flow, or pulsatile umbilical vein flow. Stage IV is defined by hydrops in one or both twins. Stage V is fetal demise in one or both twins.[1]

Maternal-fetal intervention for TTTS is a minimally invasive procedure in which a fetoscope is introduced through the mother and the uterus (Fig. 118.6). A laser is used to ablate the offending

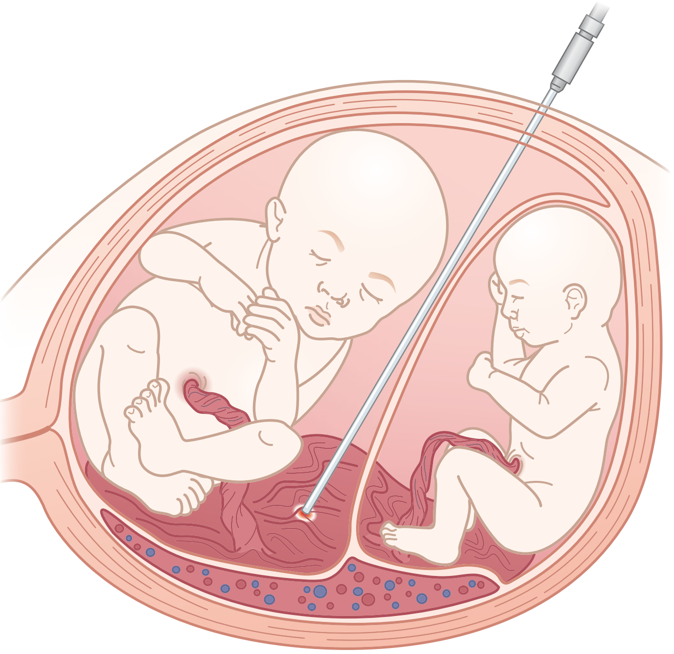

FIGURE 118.6 Laser ablation.

communicating vessels across the shared placenta. Fetal laser ablation can be performed from 16 to 26 weeks' gestation. Randomized controlled trials of laser ablation in advanced TTTS have demonstrated a significantly higher likelihood of survival of at least one twin (from about 50% to 75%) and decreased neurologic complications, although the risk of PROM and preterm delivery is increased.[48] Not all patients with TTTS may require intervention. Observational studies have supported expectant management of stage 1 TTTS, and a recent randomized trial did not show clear benefit of intervention, although it was stopped early for slow accrual. Importantly, 60% of stage 1 TTTS patients in the expectant group ultimately progressed to needing urgent intervention, reinforcing the need for close monitoring and access to a well-equipped fetal surgical center.[49]

Lower Urinary Tract Obstruction

Maternal-fetal intervention to decompress the lower urinary tract has been investigated since the origin of maternal-fetal surgery and was one of the earliest diseases in which human maternal-fetal intervention was attempted. The rationale for maternal-fetal intervention is that prenatal urinary obstruction can lead to renal dysplasia and a lack of amniotic fluid volume, leading to pulmonary hypoplasia. These potentially fatal consequences may be ameliorated by urinary tract decompression before birth.[50] A thorough understanding of the natural history of untreated fetal urinary obstruction is paramount in appropriate patient selection because the majority of fetuses with urinary tract obstruction do not require intervention.

The goal of maternal-fetal intervention is to restore amniotic fluid and prevent the development of pulmonary hypoplasia. Serial amnioinfusion is one method of increasing amniotic fluid, but it is risky and difficult to sustain long term.[51] Decompression of the bladder can be performed via cystoscopy or deployment of a vesicoamniotic shunt placed percutaneously using ultrasonographic guidance.[52] These approaches increase amniotic fluid volume by diverting the fetal urine past the obstruction to the amniotic cavity. Shunts are not fixed to the abdominal wall and are prone to dislodgement or migration. In a recent meta-analysis, 2-year pooled survival is noted to be 40% after vesicoamniotic shunting.[53] Fetal cystoscopy is performed through the abdominal wall. If a posterior urethral valve is visualized, laser fulguration can be performed. Ablation of the posterior urethral valve restores a patent urethra and has been reported to potentially restore normal fetal bladder filling and emptying.[54]

Because maintenance of normal amniotic fluid levels may subvert pulmonary hypoplasia, support was generated, and a multicenter renal anhydramnios fetal therapy (RAFT) trial (NCT03101891) was designed to evaluate the safety, feasibility, and efficacy of serial amniotransfusions for early pregnancy anhydramnios caused by bilateral renal agenesis or fetal renal failure.[55]

NOVEL THERAPIES AND FUTURE DIRECTIONS IN FETAL MEDICINE AND SURGERY

Although the past for maternal-fetal surgery has been marked by extraordinary progress in an entirely new field of medicine, it is the future that shines most brightly. From discoveries on the fetal origins of adult diseases to ever-increasing applications for fetal gene and stem cell therapies or the induction of tolerance for future transplants, the promise of fetal medicine and surgery is extraordinary and holds a lifetime of investigative promise for young scientists. As maternal-fetal surgery is evolving, promising animal work is underway exploring the technical feasibility and pathophysiologic rationale for in utero interventions.

Gastroschisis

Gastroschisis is an increasingly common congenital abdominal defect of the newborn whereby the intraabdominal organs are located outside of the abdominal cavity at birth and are not covered by an amniotic sac. Thus, the small intestine and other involved viscera are exposed to amniotic fluid and trauma in utero, which is hypothesized to contribute to postnatal intestinal dysfunction. Postnatally, this is often manifested by a thick peel on very matted intestine.[56] Although infants with gastroschisis have excellent survival, delayed gastrointestinal motility is a hallmark of the disease and leads to prolonged hospitalization and need for parenteral nutrition. There is currently no proven effective in utero intervention, but early animal studies showed that in utero surgical intervention is safe in a fetal sheep model of gastroschisis.[57] Gastroschisis is one of the leading causes of short-bowel syndrome and intestinal transplantation in children. The theoretical goal of maternal-fetal intervention is to minimize these consequences. Unfortunately, most attempts at predicting outcome by prenatal markers have been unsuccessful in identifying which patients are at high risk for postnatal morbidity. To date, maternal-fetal intervention for gastroschisis remains limited to experimental models. However, there is currently an open phase I feasibility study to evaluate fetoscopic in utero repair of complex gastroschisis.[58]

In Utero Stem Cell Transplantation

One can argue that the fetus is the ideal target for regenerative therapies for several reasons, such as the inherent regenerative milieu that is the natural fetal condition, the fetus being the ideal source of stem cells, and the fact that fetal cells possess characteristics of plasticity and differentiation capabilities that are generally superior to those of adult stem cells.[59] The most widely used stem cells have historically been bone marrow–derived hematopoietic stem cells (BM-HSCs). HSCs are able to engraft and have the potential to differentiate into blood cells, giving them the unique potential of curing hemoglobinopathies prenatally that have historically relied on postnatal bone marrow transplants. The stem cell field has recently migrated toward mesenchymal stem cells (MSCs) because they have trilineage mesenchymal potential, being able to differentiate into adipogenic, chondrogenic, and osteogenic lineages.[60] Furthermore, MSCs are known to display immunomodulatory capabilities through paracrine mechanisms, without engrafting and differentiating, and thus, they can be applied to other organ systems. Most importantly, although MSCs have been mostly derived from adult bone marrow, other sources of MSCs are increasingly available, such as MSCs derived from amniotic fluid and placenta.[56,59] HSCs and MSCs are being applied as therapeutic approaches in the treatment of hemoglobinopathies, congenital skeletal deformities, and even other developmental defects (e.g., gastroschisis).

BM-HSCs may have the potential to cure hemoglobinopathies such as sickle cell disease (SCD) and thalassemia (Thal). SCD and Thal are hemoglobinopathies arising from single-gene defects and result in life-threatening anemia.[61] The current gold standard of treatment is a postnatal human leukocyte antigen (HLA)-matched bone marrow donor transplant after myeloablative conditioning. However, SCD and Thal treatments are currently limited by the number of available matched donors. In utero hematopoietic cell transplantation (IUHCT) has been shown to offer a curative treatment. It is a nonmyeloablative approach that does not require immunosuppression and allows for mixed allogeneic chimerism to build donor-specific tolerance. This approach takes advantage of the fetus's immature immune system and induces fetal chimerism. Subsequently, a second postnatal same-donor "booster" bone marrow transplant can achieve high levels of engraftment and thus donor hemoglobin expression, correcting the phenotypes of SCD and Thal.[62] The booster strategy as a postnatal treatment is feasible because the fetus has already achieved chimerism, compatible with the donor, from the in utero IUHCT. Therefore, the neonate will accept a postnatal bone marrow transplant without rejection. This treatment then effectively expands the eligible transplant population. Alternatively, the fetus is chimeric with respect to the mother; thus, a maternal-to-fetal stem cell transplant may improve outcomes more so than a transplant from any other donor. Studies showed that high doses of maternal donor HSCs allowed for higher levels of chimerism in a fetal canine model, and a subsequent renal transplant from the same maternal donor showed no signs of rejection. Furthermore, after proven success in large animal models, an ongoing phase I clinical trial is accepting patients with Thal and aims to demonstrate the safety and efficacy of prenatal IUHCT in humans with Thal (NCT02986698). Briefly, the fetus will receive a transplant of maternal BM-HSCs intravenously via the umbilical vein. Investigators are interested in the resulting postnatal level of chimerism, which will serve as the determining factor in the continuation of such clinical trials. Thus, adult HSCs have the potential to cure hemoglobinopathies and may well become the current standard of care in years to come.

Because MSCs have shown trilineage potential, they may prove to be the ideal choice for curing congenital skeletal developmental problems or even skeletal defects, among other disorders. Osteogenesis imperfecta is a heterogeneous congenital bone disorder characterized by a defect in the type I collagen–producing gene, which mainly leads to abnormal skeletal development and painful fractures, which may begin to occur in utero. The fetus is in a state of rapid skeletal development with an immune system that has yet to develop, providing an environment ideal for MSC therapy. First-trimester fetal MSCs were used as an allogeneic treatment for osteogenesis imperfecta in a mouse model, where MSC transplantation was shown to be safe; treatment improved bone strength, length, and cortical thickness, resulting in a two-thirds reduced incidence of fractures.[63] Additionally, two human patients received intravenous prenatal and postnatal same-donor fetal MSCs. One of the patients was found to have about one fracture a year until 8 years old, at which point the patient received an additional postnatal infusion with same-donor cells. In the following 2 years, the patient was found to have no new fractures and was able to start dance classes and participate in hockey and gymnastics.[64] Therefore, MSC treatment may prove to be the superior curative option over bisphosphonates and other approaches currently used for osteogenesis imperfecta management.

MSCs are known to have other capabilities beyond the trilineage differentiation potential. Fetal MSCs have shown unique wound-healing capabilities, which may make them ideal candidates for the treatment of other birth defects, such as gastroschisis, via transamniotic stem cell therapy (TRASCET). Bowel damage was reduced in a rodent model of gastroschisis when amniotic fetal MSCs were delivered in a concentrated dose via intraamniotic injection. The rationale is that boosting the amniotic fetal MSC numbers already present in the amniotic fluid enhances the normal in utero activity.[56] Once the infant is born, they can receive postnatal surgery to enclose the abdominal viscera and close the defect. This approach takes advantage of the fetal environment by using the dual function of the amniotic fluid. Amniotic fluid causes damage to the bowel because of its inherent toxicity, but it also partakes in the healing process due to its native stem cells. By infusing the amniotic fluid with a higher dose of expanded stem cells, the wound-healing aspect of the amniotic fluid can prevail over its inherent toxicity. TRASCET technique has been applied to other models as well, including CDH, leading to a decrease in arterial wall thickness compared with the untreated group.[65]

Fetal Tissue Engineering

Tissue-engineering approaches often combine the use of a matrix with stem cells aimed at regenerating missing or malformed structural organs. Several tissue-engineering approaches have been attempted for the treatment of MMC, which is the most severe form of spina bifida. MMC is not just a neurologic disorder but a complex disease with significant deformation of bone and connective tissue overlying the spinal cord. Therefore, approaches to completely restore neurologic function must address both restoration of neural function and tissue coverage. One possible treatment involves the application of stem cells to protect neurons in combination with a scaffold to provide tissue coverage. The most promising stem cell type in the treatment of MMC has been shown to be early gestational MSCs, derived from the placenta (PMSCs). PMSCs display notable immunomodulatory properties and neuroprotective capabilities superior to those of other types of MSCs. In preclinical studies thus far, PMSCs were shown to restore motor function in a fetal sheep MMC model (Fig. 118.7).[66]

Although the PMSC–extracellular matrix (PMSC-ECM) scaffold has the potential to rescue ambulation at birth, the absent overlying spine may still allow postnatal damage to accrue and may thus compromise motor function after birth. As such, a bone scaffold seeded with PMSCs may prove to be the more comprehensive

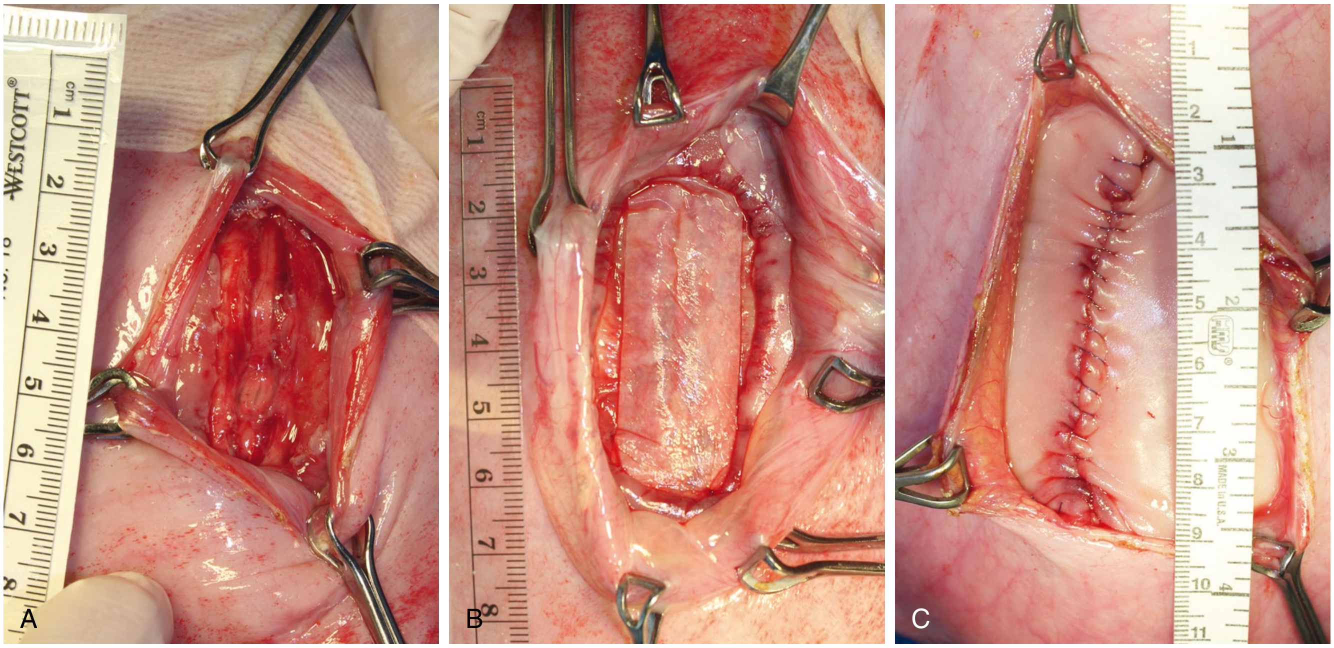

FIGURE 118.7 Placenta mesenchymal stem cell–extracellular matrix (PMSC-ECM) application for myelomeningocele (MMC) in utero—representative images. (A) The MMC defect in the fetal sheep model. (B) The PMSC-ECM patch applied during repair surgery. (C) The closure of the overall repair.

treatment in the future. The rationale is that once the PMSC-ECM patch has rescued motor function, the PMSCs on the bone scaffold may encourage tissue and bone coverage formation. Current studies are looking at developing various bone scaffolds, for example, polymer-ceramic composites, such as hydroxyapatite poly (lactide-co-glycolide), seeded with MSCs.[67]

Alternative treatments for MMC have explored other tissue-engineering approaches. One such study has engineered a gelatin-based sponge to allow sustained release of fibroblast growth factor, which enhances angiogenesis and induces fetal stem cells to regenerate a tissue layer over the MMC defect in a fetal ovine model.[68] In a separate model, PMSC-ECM has led to increased large neuron density, which correlated with improved motor function.[69] This tissue-engineering technique is an excellent example of the work done to enhance the normal fetal developmental process. Current phase I/IIa clinal trials are underway (NCT04652908) using placental-derived stems cells in fetal repair of MMC.

For CDH, tissue engineering to develop a diaphragmatic patch derived from MSCs is being actively investigated as an alternative source of bioprosthetic.[70]

In Utero Gene Therapy

In utero gene therapy orchestrates results by taking advantage of the normal developmental properties of the fetus to correct life-threatening abnormalities. The majority of gene therapy clinical trials are focused on inherited monogenic diseases. Treating most monogenic diseases involves the correction of the disorder by prenatal transfer of a functional normal gene to work in place of the defective one. One study evaluated the potential of single intrauterine gene transfer (IUGT) in a primate model of hemophilia B by assessing long-term transgene expression. The study concluded that late-gestation gene transfer via an adeno-associated vector-human factor IX (AAV-IUGT) was safe and effective.[71] However, in cases in which the addition of a functional gene is not sufficient to correct the phenotype, gene-editing tools may become more prominent. CRISPR-Cas9 technology is a gene-editing tool that shows immense potential in the therapeutic correction of monogenic disorders. Intraamniotic delivery of gene-editing reagents during fetal development was shown to result in specific gene editing of pulmonary epithelial cells in a fetal mouse model and thus corrected lung disease.[72] These results show the potential of gene-editing therapies to restore lung function and treat inherited disorders, such as cystic fibrosis. Prenatal gene editing may be beneficial because of its efficiency in rescuing fetuses from otherwise lethal diseases. However, given that the mother is a “bystander,” injection techniques and gene-editing delivery vehicles must be optimized to avoid directly affecting the mother.

ETHICS IN MATERNAL-FETAL SURGERY

A defining feature of maternal-fetal surgery is that the potential benefit for the fetal and/or neonatal patient entails risk without potential benefit for the pregnant patient. Thus, all maternal-fetal interventions require careful consideration of every aspect of care as it pertains to both the fetus and the mother. In 1982, Harrison and colleagues established a series of guiding principles for maternal-fetal surgery, of which the key principles hold true today.[73] Among them was the recognition that maternal-fetal surgery is complicated, not only by the risk to the fetus but also by the risk to the pregnant patient as well.

The American College of Obstetricians and Gynecologists (ACOG) has provided guidelines for fetal centers to navigate these ethical considerations.[74] The ACOG recommends a multidisciplinary team approach, including maternal-fetal medicine specialists, neonatologists, pediatric surgeons, and ethicists. This team ensures that all aspects of care, from the medical evaluation to ethical decision-making, are addressed comprehensively. The complexities of maternal-fetal surgery necessitate close collaboration among multidisciplinary teams, which should possess not just the technical expertise for performing the procedure on both the pregnant patient and fetus but also a profound grasp of pregnancy physiology and fetal pathophysiology.

The central ethical principle in maternal-fetal surgery revolves around the balance between beneficence and respect for the autonomy of the pregnant patient. Although the procedure may offer life-altering benefits for the unborn child, it often entails significant risk to the pregnant patient, raising questions about the ethical permissibility of such interventions. Dr Michael Harrison's insistence on a multidisciplinary team approach cannot be emphasized enough because it helps in carefully assessing the risks and benefits, considering the maternal patient values, and making informed decisions that prioritize the welfare of both the pregnant patient and fetus. Ethical discussion must be an integral part of the decision-making process, ensuring that the mother's autonomy is respected and her well-being is upheld.[75]

CONCLUSION

As evidenced throughout this chapter, incredible treatments and techniques have been developed to treat serious fetal conditions. As new technology emerges, rigorous science continues, and advancements are made at a rapid pace. True innovation in maternal-fetal surgical techniques would not be possible without multidisciplinary collaboration with neonatologists, perinatologists, radiologists, and anesthesiologists, along with innovation with biomedical partners. Ultimately, the past, present, and future success of maternal-fetal surgery can be credited to the extraordinary bravery of the mothers willing to endeavor and trust in a promising field for the improved prognosis of their future child.

BASIC ANATOMY

Anatomic Terms and Biomechanical Movements

The upper extremity has unique anatomic terms as well as descriptions of movements because of its mobility in relationship to the axial skeleton at the shoulder, the ability of the forearm to be pronated and supinated, and individual finger movements and thumb opposition. The upper extremity can be broken up into major regions, including the shoulder, arm, elbow, forearm, wrist, and hand. The majority of procedures performed by hand specialists are from the elbow to the fingertips, so this chapter will focus on regional anatomy distal to the elbow.[1]

Anatomic position of the arm and forearm is supinated with the palm facing forward, so the palm is anterior, and the back of the hand, or dorsum, is posterior. The more appropriate terminology is *volar* (or *palmar*) for the palm surface and *dorsal* for the posterior surface. The medial and lateral aspects are better termed *ulnar* and *radial,* respectively, with thumb radial and small finger ulnar. Within the extremities, those structures closer to the axial skeleton are termed *proximal,* whereas those toward the end of the extremity are *distal.* Motion in a palmar direction is *flexion,* whereas dorsal motion is termed *extension*. In the forearm, supination moves the forearms and hands into anatomic position so that the palms face forward and the radius and ulnar are parallel; pronation moves the palms and forearms to face posteriorly, and the radius and ulna overlap. Finger motion away from the long finger axis is termed *abduction,* whereas motion toward the axis of the long finger is termed *adduction.* The description of the motion of the thumb must take in to account another plane of movement—*opposition,* or bringing the tip of the thumb to face the other digits, such as occurs with pinching motions. Extension of the thumb is dorsally out of plane with the hand. Motion in the same plane as the hand is termed *abduction* (away from) or *adduction* (toward) the palm. The surface anatomy of the volar and dorsal hand is shown in Fig. 119.1.

Bony Anatomy

It is important to understand the basic bony anatomy of the forearm and hand, especially because certain bony landmarks will guide surface examination and procedures. The forearm contains two long bones, the radius laterally and the ulna medially. Between these two bones runs the interosseous membrane, which separates the volar flexor structures and the dorsal extensor structures. At the distal aspect of the forearm, the radius and ulna articulate at the distal radioulnar joint, which allows for stability and support of the pronation and supination at the wrist.

The bony wrist, or carpus, is made up of eight different carpal bones. The proximal row consists of the scaphoid, lunate, and triquetrum (from radial to ulnar). The distal carpal row includes the trapezium, trapezoid, capitate, and hamate. The pisiform is a sesamoid bone within the tendon of flexor carpi ulnaris (FCU). The multiple small carpal bones allow the wrist a unique and wide range-of-motion capabilities (Fig. 119.2).

The hand consists of five metacarpal bones. The first metacarpal is unique because it forms a saddle joint with the trapezium, which allows for the thumb range of motion both in plane and out of plane of the hand. Each digit is made up of small long bones called the *phalanges.* The thumb has two phalanges, proximal and distal, and the four fingers each have three phalanges, proximal, middle, and distal. There are many articulations, so the easiest terminology is to use abbreviations—the carpometacarpal joint is the CMCJ, the metacarpophalangeal joint is the MCPJ, and similarly for proximal interphalangeal joint (PIPJ) and distal interphalangeal joint (DIPJ) (see Fig. 119.2).

Muscles and Tendons of the Forearm and Hand

The muscles of the hand and forearm can be divided into *intrinsic,* those originating and inserting within the hand, and *extrinsic,* muscle bellies in the forearm and insertions in the hand. The extrinsic muscles comprise the long flexors and extensors of the wrist and digits. The extrinsic muscle bellies can be divided into three forearm compartments: the volar compartment, the dorsal compartment, and the mobile wad. The volar compartment can

FIGURE 119.3 A graphical illustration of the muscles and tendons that give effect to prehensile movements of the human hand. These are shown in dorsal aspect (A) and palmar aspect (B). It can be seen that articulations of the hand form functional groups arranged in kinetic chains. These are subject to control via synergies constituted by the organized recruitment by the central nervous system of muscles extrinsic to the hand and muscles intrinsic to the hand that, when coordinated, permit the differentiated action of the phalanxes. (From Carson RG. Get a grip: individual variations in grip strength are a marker of brain health. *Neurobiol Aging*. 2018;71:189-222.)

be further subdivided into superficial, intermediate, and deep layers (Fig. 119.3). The superficial layer comprises the pronator teres, flexor carpi radialis (FCR), palmaris longus, and FCU. The palmaris longus muscle may be absent in as many as 10% to 15% of individuals. The intermediate layer consists of the flexor digitorum superficialis (FDS), which flexes the PIPJ, and the deep layer consists of the flexor pollicis longus (FPL), which flexes the thumb interphalangeal joint (IPJ); the flexor digitorum profundus (FDP), which flexes the DIPJ; and the pronator quadratus.

The finger flexors in the digit are surrounded by the flexor tendon sheath. There are five annular and three cruciate pulleys on each finger, numbered A1–A5 and C1–C3, respectively, starting from proximal to distal, with the A1 pulley at the MCPJ and odd-numbered pulleys at the PIPJ and DIPJ, respectively (Fig. 119.4).

The radial most subgroup is termed the *mobile wad* and comprises the brachioradialis, a weak elbow flexor that does not move the hand or wrist, extensor carpi radialis longus (ECRL), and extensor carpi radialis brevis (ECRB), which extend the wrist and deviate it radially. The dorsal compartment also can be subdivided into superficial and deep layers. The superficial layer is made up of the extensor digitorum communis (EDC), the extensor digiti minimi (EDM or EDQ, for *extensor digiti quintus*), and the extensor carpi ulnaris (ECU) (see Fig. 119.3C). The ECU deviates the wrist in an ulnar direction and extends the wrist; the EDM and EDC extend the digits via a complicated insertion mechanism known as the *extensor hood.* The third and deeper subgroup is composed of four muscles (see Fig. 119.3D): the abductor pollicis longus (APL), extensor pollicis brevis (EPB), and extensor pollicis longus (EPL) provide function to the thumb, and the extensor indicis proprius (EIP) acts as a redundant extender of the index finger, giving it the greatest ability to individually extend. Last of the deep muscles is the supinator, which is located proximally in the forearm.

The extensor tendons pass through six compartments deep to the extensor retinaculum at the dorsum of the wrist (Fig. 119.5). The first compartment contains APL and EPB, forming the radial boundary of the anatomic snuffbox. The second compartment consists of the ECRL and ECRB, and the third compartment contains the EPL, forming the ulnar border of the anatomic snuffbox. The third compartment crosses over the second and partial fourth compartment. The EIP and EDC pass through the fourth compartment; the EDM passes through the fifth compartment, where they overlie the distal radioulnar joint; and the sixth compartment contains ECU.

At the level of *the metacarpophalangeal joints (MPJs),* the long extrinsic extensor tendons broaden out to form the extensor hood (Fig. 119.6). The proximal part of the hood at the level of the MCPJ is called the *sagittal band.* It loops around the MPJ and blends into the volar plate, thus forming a lasso around the base of the proximal phalanx, through which it extends the MPJ. The insertions of the interossei and lumbricals enter the extensor hood as the lateral bands and insert distally and dorsally to the axis of the PIPJ. It is through this distal insertion that the intrinsic muscles (the interossei and lumbricals) are flexors of the MPJs and yet extensors of the IPJs. The extensor hood inserts to the base of the middle phalanx, which is termed the *central slip,* and finally proceeds on to the base of the distal phalanx, where it inserts through the terminal slip, thus extending the DIPJ.

The intrinsic muscles of the hand are responsible for the fine motor movements of individual digits, especially the thumb (Fig. 119.7). The intrinsic muscles of the thenar eminence are the abductor pollicis brevis (APB), flexor pollicis brevis, opponens pollicis, and adductor pollicis. Four lumbricals originate on the FDP

tendons in the palm and insert on the radial sides of the extensor mechanisms of the four fingers (see Fig. 119.7B). There are four dorsal interossei that arise from adjacent sides of each metacarpal and insert onto the base of the proximal phalanx and lateral extensor hood of the ulnar digit; these provide abduction of the MCPJs of the index, middle, and ring fingers. There are three palmar interossei that adduct the index, ring, and little fingers toward the middle finger (see Fig. 119.7C). Together with the lumbricals, these bring about flexion of the MPJs and extension of the IPJs of the fingers. The flexor pollicis brevis flexes the thumb at the MPJ, whereas the extrinsic FPL flexes the thumb at the IPJ.

The hypothenar muscles consist of the flexor digiti minimi, which flexes the little finger at the MPJ, and the abductor digiti minimi and opponens digiti minimi. A small muscle called the

FIGURE 119.7 (A–B) Intrinsic muscles of the hand (volar) and relationship to neurovascular structures. Schema of the lumbrical muscles and interossei. (From Neuman DA. *Neumann's Kinesiology of the Musculoskeletal System*. 4th ed. St. Louis: Elsevier; 2025.)

palmaris brevis is located transversally in the subcutaneous tissue at the base of the hypothenar eminence. It is innervated by the ulnar nerve, puckers the skin, and helps in cupping the skin of the palm during grip (see Fig. 119.7A).

Innervation of the Forearm and Hand

The hand is innervated by three nerves, the median, ulnar, and radial nerves (Fig. 119.8). These nerves originate at the brachial plexus and extend distally into the forearm and hand. The median nerve originates from the medial and lateral cords of the brachial plexus, supplied by C6–C8, and in the forearm, it runs midline between the FDS and FDP muscle bellies. The median nerve supplies the palmaris longus (PL), FCR, FDS, FDP to the index and long finger, pronator teres, and FPL in the forearm. The median nerve enters the hand via the carpal tunnel, along with nine tendons (FDS, FDP, FPL). The median nerve passes through the carpal tunnel between its ulnar attachments to pisiform and hamate and radial attachments to trapezium and scaphoid tubercle. The sensory aspect of the nerve gives sensation to the thumb, index finger, middle finger, and radial half of the ring finger. The palmar cutaneous branch of the median nerve originates from its radial side 5 to 6 cm proximal to the wrist, providing sensation to the palmar triangle. The median nerve gives off a motor branch at the level of the carpal tunnel, which supplies the thenar muscles, including FPB, OP, and APB as well as the radial two lumbricals to the index and middle fingers (see Fig. 119.8A).

FIGURE 119.8 Nerve anatomy of the upper extremity. *a.*, Artery; *aa.*, arteries. (From Feldscher SB, et al. *Rehabilitation of the Hand and Upper Extremity.* 7th ed. St. Louis: Elsevier; 2021.)

The ulnar nerve has contributions from C7–T1 and originates from the medial and small amount of the lateral cord of the brachial plexus. In the arm, it courses medially and posterior to the medial epicondyle of the humerus before coursing more volarly into the forearm. It provides motor branches to the ulnar aspects of FDP and FCU and a dorsal sensory branch at the distal forearm, which supplies the ulnar/dorsal aspect of the hand and the dorsal aspects of the small and ring fingers. The ulnar nerve enters the wrist and hand along with the ulnar artery through Guyon's canal, which lies between the hook of hamate and the transverse carpal ligament. The sensory aspect of the ulnar nerve supplies the ulnar half of the ring finger and the small finger, and the motor branches supply the intrinsic muscles of the hand, including all interossei, the ulnar two lumbricals, the hypothenar muscles, and adductor pollicis (see Fig. 119.8B).

The radial nerve begins as the direct continuation of the posterior cord of the brachial plexus (C5–T1) and moves from anterior to posterior within the spiral groove of the humerus at the mid-humeral shaft. Once in the forearm, the nerve travels deep to the two heads of supinator muscle, becomes the posterior interosseous nerve (PIN), and sends motor branches to all the extensors and supinators of the wrist and hand. The terminal branch of the PIN innervates the dorsal wrist capsule. The superficial radial sensory nerve emerges from under the brachioradialis in the distal forearm, dividing into two or three branches proximal to the radial styloid that then proceed in a subcutaneous course across the anatomic snuffbox, innervating the skin of the dorsum of the first web space and the majority of the dorsum of the hand (see Fig. 119.8C).

Vascular Supply and Venous Drainage

The blood supply and venous drainage of the upper extremity are relatively simple (Fig. 119.9). The subclavian artery becomes the axillary artery after crossing the pectoralis minor, and the axillary artery becomes the brachial artery after crossing the teres major muscle. The brachial artery then splits into the radial and ulnar arteries distal to the antecubital fossa. The radial artery at the wrist travels deep and slightly ulnar to FCR tendon, and the ulnar artery travels within Guyon's canal radial to the hook of hamate. Both arteries form two anastomotic arches, the superficial and deep palmar arches, which branch to form the common digital arteries. These split into two proper digital arteries for each digit and run radial and ulnar to the flexor sheath on the volar aspect of each finger. The deep venous drainage system follows the nomenclature of the arteries, with two venae comitantes running with each major artery. The superficial venous drainage sends tributaries starting at the dorsum of the hand and drains into the basilic (ulnar) and cephalic (radial) systems.

EXAMINATION AND DIAGNOSIS

General Evaluation

Many of the most common diagnoses and injuries of the hand and upper extremity can be determined clinically based on a thorough patient history and physical examination. Because hand surgery is a regional discipline, there are multiple systems that must be assessed to be normal in function: skeletal, muscle, neurologic, vascular, and skin/soft tissue. Patient history will provide invaluable clues to the diagnosis. Some key points of information include mechanism of injury; date and/or time of injury; hand dominance, which may affect the urgency of intervention; occupation or daily activities, which may affect return to work; baseline level of function; and previous hand injuries or surgeries that may have left a lasting deficit unrelated to the current presenting problem.

There are a few specialized instruments that may be used in the general physical examination; however, the most informative actions will be visualization and palpation of the structures of the hand. The first step is inspection, or simply looking at the extremity. Are there any lacerations, edema, or obvious deformities? Examination of the resting posture of the hand can provide valuable information—the flexors are more robust than the extensors, and therefore, the resting posture of the fingers should be flexed in a "cascade" in which all digits point slightly to the scaphoid or radial aspect of the wrist (Video 119.1). Angulation or malrotation from digital or metacarpal fractures/dislocations or flexor or extensor tendon injuries can affect cascade. Color changes such as pallor or ecchymosis may indicate vascular injury or long bone fracture. Swelling and erythema may indicate a hand infection. It is additionally important to note any scars present because they may indicate preexisting injury or previous surgery.

Musculoskeletal Examination

Palpation is important to physical examination. Fig. 119.10 shows typical bony landmarks on x-ray, which can be correlated to physical examination. If assessing an elective or subacute patient, bony landmarks and joints should be individually assessed by palpation and range of motion. Tenderness of joints to palpation can indicate arthritis; laxity on movement of a joint can indicate collateral ligament injury. Table 119.1 shows, in more detail, examination of common joint pathologies, such as thumb carpometacarpal (CMC) arthritis. Range of motion for the focal parts of the upper extremity should be assessed (except for an acute fracture), including pronation/supination for forearm pathology, wrist extension/flexion and radial/ulnar deviation, and range of motion of all digits (Video 119.2). Table 119.2 details normal ranges of motion for different joints of the hand and wrist, and Video 119.3 shows a basic surface wrist examination. Because the wrist contains eight different carpal bones and a multitude of ligaments, a thorough wrist examination can be a key part of making the diagnosis of a patient with a fall or wrist pain (see Table 119.2).

The most basic muscle, tendon, and neurologic hand examination includes three active movements from the patient: making a fist (flexion), making a "thumbs-up" motion (thumb abduction and extension), and making an "A-OK" sign (thumb opposition and intrinsic function, extension of ulnar digits). In noncooperative, unconscious, or pediatric patients, assessment of digital tendons can be accomplished using tenodesis examination—the digits should flex with passive wrist extension and extend with passive wrist flexion, and this can be performed surreptitiously without causing the patient pain (see Video 119.1). Squeezing the forearm can also initiate flexion. More detailed examination

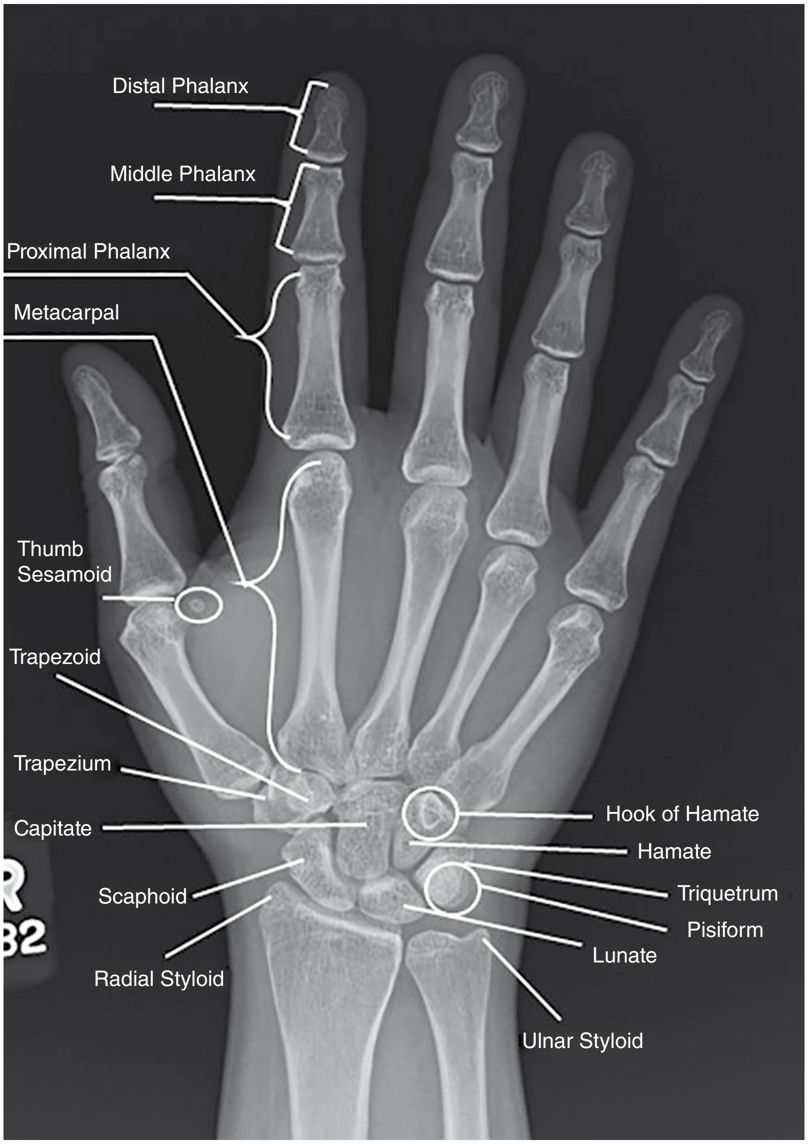

FIGURE 119.10 Anteroposterior view x-ray of a normal hand with common anatomic landmarks labeled on the read.

TABLE 119.1 Hand Examination Special Maneuvers

TEST NAME	INDICATION	TECHNIQUE	POSITIVE FINDING
Thumb CMC grind	Suspicion of thumb CMC arthritis	Axial loading of the thumb and gentle circumduction at CMC joint	Sensation of grittiness or crepitus within the joint. May also have pain; should compare to contralateral.
Finkelstein test	Suspicion of De Quervain tenosynovitis	Have the patient flex the thumb into the palm and wrap the other digits around it in flexion; then have them relax and passively ulnarly deviate the wrist.	Sharp pain on ulnar deviation. May also have tenderness to palpation over radial styloid.
Watson test	Assess scapholunate ligament laxity or injury	Examiner places thumb over scaphoid tubercle at volar aspect of wrist while the digits stabilize on the dorsal side of the wrist and apply pressure to the scaphoid tubercle. With other hand on the patient's metacarpals, bring the hand from extension and ulnar deviation into flexion and radial deviation, with constant pressure on the scaphoid.	Examiner will feel a "clunk" as the scaphoid returns to anatomic position with the applied volar pressure on radial deviation. There may also be pain, but the test itself can be uncomfortable. Contralateral side should be tested for comparison.
L-T ballottement test	Assess lunotriquetral ligament instability or injury	With patient elbow on table and wrist neutral, the examiner pinches triquetrum and lunate between thumb and index of each respective hand, and then attempts to move them in opposing volar/dorsal direction.	Significant ballottement or laxity indicates ligament weakening or injury, particularly in the volar direction.
Anatomic snuffbox	Radial-sided wrist pain	Anatomic snuffbox is bordered by the first dorsal compartment (APL/EPB) and third dorsal compartment (EPL). Patient may radially deviate wrist and extend thumb.	Tenderness to palpation may indicate scaphoid fracture or other scaphoid pathology.

APL, Abductor pollicis longus; *CMC,* carpometacarpal; *EPB,* extensor pollicis brevis; *EPL,* extensor pollicis longus.

TABLE 119.2 Normal Range-of-Motion Ranges for Finger and Wrist Joints

JOINT	MAXIMUM EXTENSION	MAXIMUM FLEXION
Digit DIPJ	0°	80°
Digit PIPJ	0°	100°
Digit MCPJ	–45° (hyperextension)	90°
Thumb IPJ	–15° (hyperextension)	80°
Thumb MPJ	10°	55°
Wrist	–70°	75°
	MAXIMUM RADIAL DEVIATION	**MAXIMUM ULNAR DEVIATION**
Thumb CMC	60°	45°
Wrist	20°	35°
	MAXIMUM PRONATION	**MAXIMUM SUPINATION**
DRUJ	70°	85°

CMC, Carpometacarpal; *DIPJ,* distal interphalangeal joint; *DRUJ,* distal radioulnar joint; *IPJ,* interphalangeal joint; *MCPJ,* metacarpophalangeal joint; *MPJ,* metacarpophalangeal joint; *PIPJ,* proximal interphalangeal joint.

should be tailored to the presenting symptoms. The tendons of the digits should be assessed independently (Video 119.4). Flexion at DIPJ, or IPJ of the thumb, with the PIPJ held in extension confirms that the FDP and FPL, respectively, are intact (Fig. 119.11). To isolate the FDS, the digits not being examined should be held in extension because the FDP has a common muscle belly. To assess EPL and EPB, the patient should be asked to place the hand on a flat surface and lift the thumb only off the surface (Fig. 119.12A). To test for PL presence, have the patient oppose the thumb and small finger and flex the wrist (see Fig. 119.12B).

Finger extension is tested by asking the patient to extend the MCPJ against resistance. Central slip injuries can be difficult to identify and require isolation of that portion of the extensor hood with an Elson test (Video 119.5). Normally, the DIPJ is lax with the PIPJ in flexion, but in a positive test, the DIPJ can be actively extended because of slack in the lateral bands.

Neurovascular Examination

On general inspection, color changes of the digits may indicate ischemia or congestion. Capillary refill is the key to assessing perfusion of the hand—the digits are gently pressed and released to observe the return of normal coloration after blanching under pressure, normally less than 2 seconds. The Allen test confirms patency of the ulnar and radial arteries (Video 119.6). This can be especially important if assessing for major bleeding in the forearm, to determine whether a vessel may be ligated in the setting of acute trauma without compromising the hand. If there is question about perfusion, bedside Doppler ultrasound can be used to further assess pulse in the forearm vessels, palmar arches, and the radial and ulnar digital arteries.

Specific nerves should be assessed for injury by using sensory and motor territories specific to these nerves (Fig. 119.13). Sensory examination should be performed before administration of local anesthesia for any bedside procedures. Two-point sensory discrimination is the most sensitive method of testing for sensory loss and is easily done by using a two-point discrimination tool or a bent paper clip set to approximately 5 mm apart. The radial and ulnar aspects of each digit's volar fingertip should be tested. The points are aligned along the axis of the finger. If this test is not reproducible because of an uncooperative patient, suspicion of a nerve injury can be confirmed by the tactile adherence test, in which a plastic pen is passed back and forth gently across the pulp on either side of each finger. Adhesion, because of the presence of sweat, is shown by slight but definite movement of the finger being examined (anesthetized finger pulp will not sweat).

Motor function of the median nerve can be best assessed by looking at the thenar muscles and the FDS to index finger. The motor function of the APB tests the median nerve. With the hand flat and facing palm up, the patient is asked to use their thumb to touch the

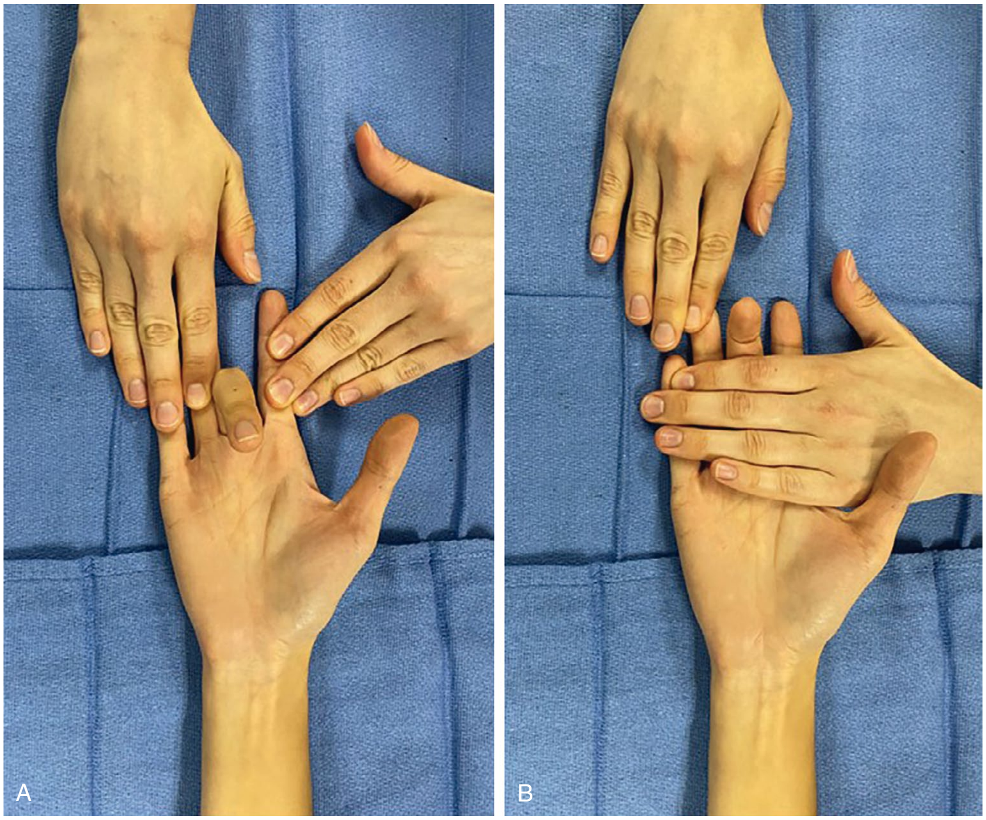

FIGURE 119.11 Isolation testing the flexor digitorum superficialis (A) and flexor digitorum profundus (B) tendons of individual digits. Note that each digit must be isolated as well as each joint to ensure accurate examination and no confounding movement from neighboring digits.

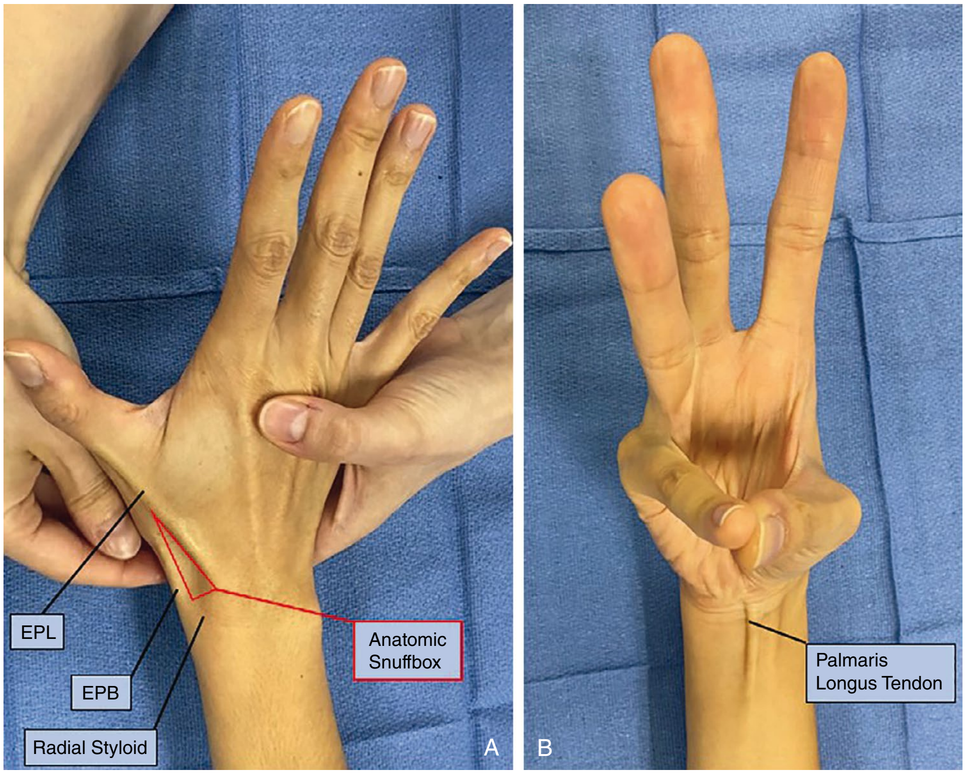

FIGURE 119.12 Dorsal wrist tendon examination including the anatomic snuffbox (A), bordered by the first and third dorsal compartment tendons (extensor pollicis brevis *[EPB]* in *1* and extensor pollicis longus *[EPL]* in *3*) and radial styloid proximally. (B) Examination of the palmaris longus tendon, with thumb/small finger opposed and wrist flexed.

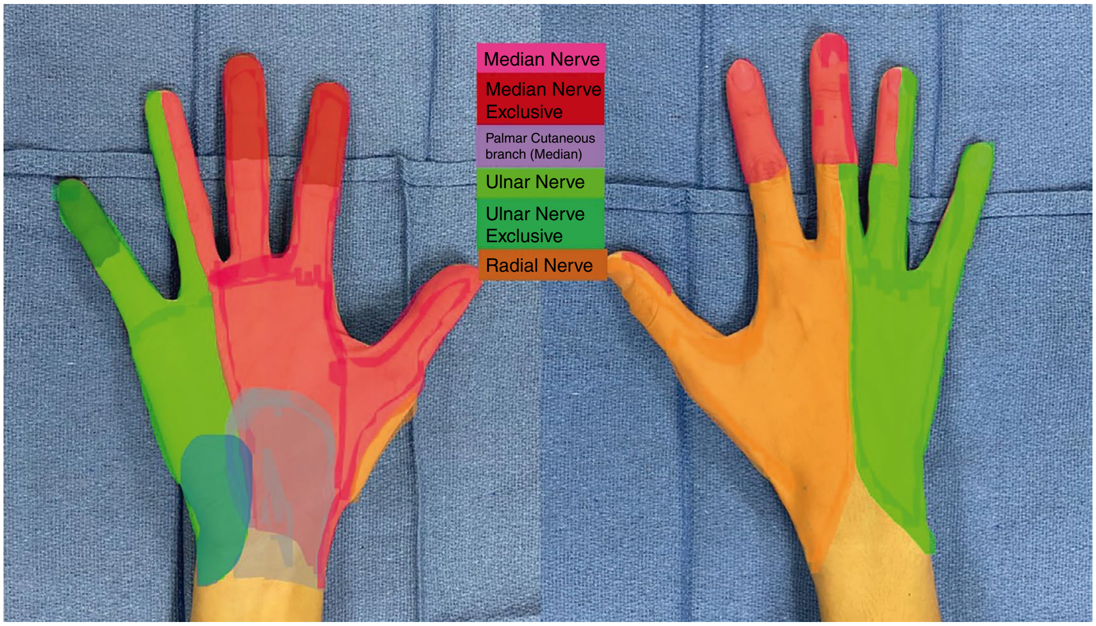

FIGURE 119.13 Sensory distribution of the nerves of the hand, including median, ulnar, and radial nerves, on examination.

examiner's finger, which is held directly over the thenar eminence.[2] Testing FPL with thumb interphalangeal (IP) flexion against resistance and FDS and FDP of index finger with resisted flexion can delineate median pathology in the wrist versus more proximally. The ulnar nerve controls hand intrinsic muscles, so simple tests include having the patient spread (abduct) the fingers against resistance and crisscross groups of fingers, testing the dorsal and palmar interossei, respectively. Thumb adduction is assessed with Froment sign, and weakness of the hypothenar muscles is assessed with Wartenberg sign. Tests for function of the radial nerve and its branches require wrist extension, thumb extension, and finger extension at the MPJ. A basic carpal tunnel examination can be seen in Video 119.7, and additional specialized neurologic tests are shown in Table 119.3.

Special Investigations and Imaging

Plain radiographs should be performed in emergency room or trauma cases and in elective patients with joint pain or suspicion of fracture. These help in the diagnosis and evaluation of fractures and arthritis and in the investigation of radiopaque foreign bodies.[3] An appropriate imaging series includes an anteroposterior (AP) view, oblique view, and true lateral view, the quality of which can be assessed based on the visibility of the pisiform bone (Fig. 119.14). Other views may be able to elucidate more specific pathologies, such a scaphoid view, clenched-fist view, or carpal tunnel view. Stress radiographic views and cineradiography may be useful for demonstrating dynamic wrist instability patterns, especially scapholunate separation.

TABLE 119.3 **Specialized Neurologic Tests for the Hand and Upper Extremity**

TEST NAME	INDICATION	TECHNIQUE	POSITIVE FINDING
Tinel sign	Assess nerve compression, assess regeneration along peripheral nerve	Gently tap with two fingers over anatomic sites of compression—carpal tunnel, Guyon canal, cubital tunnel, supinator, etc.	Reproduction of numbness and tingling and/or pain in the affected nerve distribution
Durkin compression test	Suspicion of carpal tunnel syndrome	Compress the median nerve within carpal tunnel with the thumb over the palm and the patient's wrist in neutral position	Reproduction of numbness, tingling, or pain in the median distribution of the digits; may take up to 30–60 sec
Phalen test	Suspicion of carpal tunnel syndrome	Have patient flex the wrist as much as possible so that both dorsal hands are in contact, hold position for 30–60 seconds, which will cause constriction of the transverse carpal ligament	Reproduction of numbness or tingling or pain in the median distribution of the digits; may take up to 30–60 sec
Hyperflexion test	Suspicion of cubital tunnel syndrome	Hyperflexion of the elbow as much as possible with shoulder flexed at 90 degrees	Reproduction of pain, numbness, or tingling over the ulnar nerve distribution
Froment sign	Ulnar neuropathy	Test thumb adduction by having the patient grasp something, like a sheet of paper, between the thumb and index finger metacarpal	Should be able to grasp the paper with the thenar adductor alone. Positive test is flexion of the thumb IP joint, which uses the median innervated FPL.
Wartenberg sign	Ulnar neuropathy	Observation of ulnar drift of the small finger (away from the ring finger)	Drift indicates weakness of the ulnar innervated intrinsics and pull of the radially innervated EDC/EDQ

EDC, Extensor digitorum communis; *EDQ,* extensor digitorum quintus; *FPL,* flexor pollicis longus; *IP,* interphalangeal.

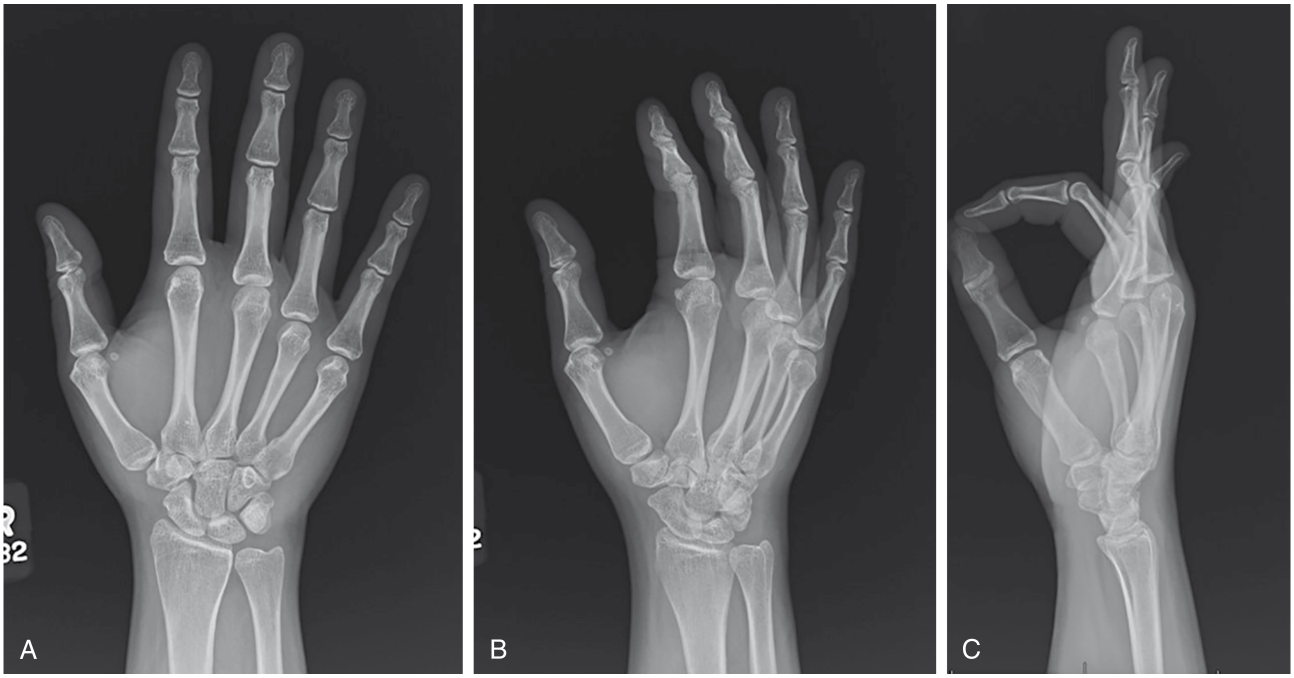

FIGURE 119.14 Standard anteroposterior (A), oblique (B), and lateral (C) radiographs of the hand. Note in the lateral view that the pisiform is centralized between the scaphoid and capitate, which determines a technically well-done lateral view.

Ultrasound is a portable, low-cost, and easy-to-use adjunct. Ultrasound has been used to assess soft issue and nerve pathologies such as carpal tunnel syndrome, trigger fingers, and other tenosynovitis.[4,5] Ultrasound can reliably show wood and plastic foreign bodies that may not show up on plain films in the hands of an experienced operator.

More complex imaging, such as CT and MRI, is typically not first line but does have important roles in hand surgery. When further bony imaging is needed for things like complex and intraarticular fractures, CT is usually the examination of choice.[6] MRI is a more appropriate examination for any masses and unclear soft tissue pathology, such as ligaments, flexor tendon sheaths, triangular fibrocartilage complex (TFCC) injuries, or detailed cartilage examination.[7] Both MRI and CT can be formatted as arthrograms to provide a detailed, noninvasive examination of the wrist, such as in concern for scapholunate ligament injury. Both CT and MRI are a useful modality for the diagnosis of a suspected carpal bone fracture.

More invasive imaging and testing include wrist arthroscopy and angiograms. With the use of CT and MRI angiograms with contrast administration, need for surgical angiograms has reduced, except for those with suspicion of complex vascular pathology, such as pseudoaneurysm. Wrist arthroscopy is the gold standard for looking at and intervening on the TFCC and scapholunate ligament. Electromyography and nerve conduction studies are other more involved tests that may be useful in patients with nerve injuries or suspected but unclear nerve compression pathology.

PRINCIPLES OF TREATMENT

Appropriate treatment of upper extremity problems requires a thorough knowledge of local and regional anesthesia, use of a tourniquet to provide a bloodless field, correct placement of incisions to minimize later scar contracture, and appropriate use of dressings and splints to reduce edema and maintain a functional position. Above all, a clear knowledge of the unique anatomy of the hand and upper extremity not only aids in obtaining an accurate clinical diagnosis but also enables the safe performance of surgery.

Anesthesia

The choice of general, regional, or local anesthesia is governed by the extent and length of the operation, in addition to patient factors such as comorbidities, anticoagulation, and pain tolerance. An upper arm or forearm tourniquet can be used in the unanesthetized extremity with only local anesthetic field infiltration or digital block for up to 30 to 45 minutes in a relaxed, cooperative patient. For ancillary procedures, such as for harvesting of bone, nerve, tendon, or skin graft, or if more extensive surgical procedures are planned, general anesthesia will be required. Wide-awake local anesthesia, no tourniquet (WALANT) procedures are becoming increasingly common in office and ambulatory settings to minimize excessive costs and risks of anesthesia. WALANT anesthesia works well for procedures such as open carpal tunnel release, mass removal distal to wrist, and trigger finger/A1 pulley releases.[8–10]

A digital block is a useful tool for finger injuries, especially in the emergent setting. Dogma states to avoid use of epinephrine in the digits because of the risk of ischemia; however, recent data suggest that there is no increased risk of loss of digital perfusion.[11] Median, ulnar, or radial wrist nerve block may be useful, and all three may be anesthetized at the wrist for a total wrist block (Fig. 119.15). Hematoma blocks can assist in fracture reductions.[12]

Tourniquet Application

The tourniquet is used to provide a bloodless field so that all relevant structures in the operative field can be visualized.[13] Especially in the emergency setting, when a formal tourniquet may not be available, common items like Penrose drains or the fingers of a sterile glove can be used for digital tourniquet. Tourniquet use is not without risk—direct pneumatic pressure can cause

damage to underlying nerves and vessels; prolonged distal ischemia can result in venous congestion or muscle damage and reperfusion injury after release. The skin below the tourniquet must be padded to prevent pressure injury or blistering, and a watertight seal such as tape or draping should be applied to prevent the underlying skin from getting wet during preparation. The standard pressure is 250 mm Hg, or 100 to 150 mm Hg higher than systolic blood pressure.[14] Historically, maximum tolerable ischemia time is 2 hours; after that point, the cuff is deflated for at least 15 minutes to allow return of blood flow.[13] An Esmarch or Martin bandage is used to exsanguinate the extremity before tourniquet inflation, except in the case of active infection or tumors because of the possibility of embolic spread from distal to proximal. In these cases, the extremity can be elevated for 5 minutes before pneumatic inflation.

Incisions

It is important to design all incisions with the promise of scar contracture in mind. On the palmar surface, Bruner, midaxial, Z-plasty, or a combination of these should be used to avoid longitudinal linear incisions that cross joints. Existing lacerations can be incorporated (Fig. 119.16).[15] On the dorsum, linear incisions may be used because the skin is laxer. The marginal edge of a skin graft with healthy skin is also a potential scar line, so the margin of the skin graft is designed to be in these same lines to prevent contractures across flexion creases if possible.

Dressings and Splints

Dressings and splints are designed for the protection of the injury or surgery site and the comfort of the patient. Any incision,

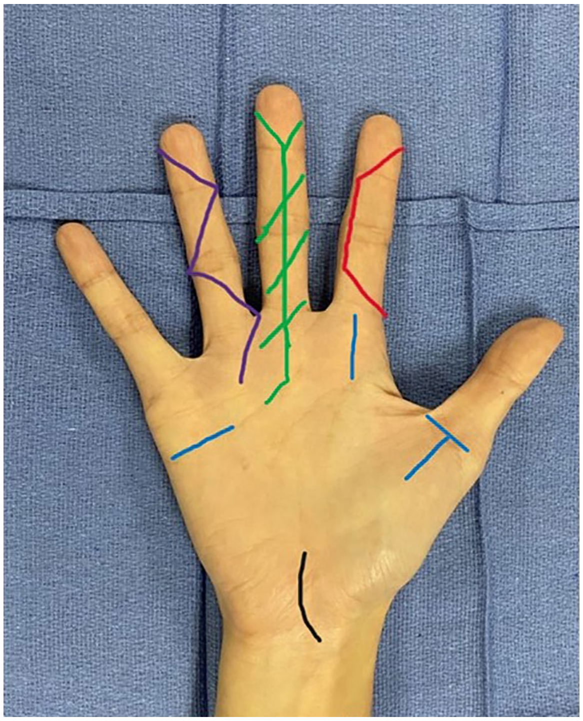

FIGURE 119.16 Appropriate incision types over the volar surface of the hand, including, from *left* to *right,* Brunner incision, Z-plasty–style incisions, and midaxial incision. The *blue lines* indicate potential placement of trigger finger incisions, horizontally or vertically, and the *black line* indicates a typical open carpal tunnel incision.

laceration, or open wound should be covered with a nonadherent layer of gauze. Soft, bulky dressings with conforming wrap are all that is necessary for procedures that do not have bony or tendon involvement. Splinting or casting provides key immobilization for fractures as well as fresh tendon repairs to ensure that tissues have a chance to heal and scar in proper position. The immobilizer should be designed to only immobilize the intended structure, with minimal impingement on uninvolved structures. Immobilizing materials include plaster and fiberglass, and thermoplastic custom splints are available in some settings. Fingers can be splinted easily with aluminum or prefabricated plastic splints. Common types of splints that may need to be applied in the emergency department (ED) are described in Table 119.4. In a routine splint, to prevent unwanted wrist and digital stiffness or contracture,

TABLE 119.4 Common Splints for Upper Extremity

SPLINT TYPE	COMMON USES	AREA IMMOBILIZED	DIAGRAM
Volar resting	Minimally displaced fractures, carpal fractures, carpal tunnel syndrome, comfort (nonstrict immobilization)	Midforearm to metacarpals with flexion blockage, can be extended to include finger joints. Use intrinsic plus position.	Ulnar gutter	Small or middle metacarpal fractures, ulnar-sided carpal or proximal phalanx fractures	Distal one-third forearm to middle phalanx, ulnar aspect of wrist, hand; may be extended to DIPJ for phalanx fractures.	Thumb spica	Thumb phalanx or metacarpal injuries, suspicion or actual scaphoid fracture	Midforearm to thumb, including IP joint. Thumb in abduction.	Clamshell or volar/dorsal	Distal radius fractures	Proximal one-third of forearm (not impinging on elbow) to MCPJ, volar and dorsal slab. Intrinsic plus positioning of wrist.	Sugar-Tong	Distal radius and radial or ulnar shaft fractures	Dorsal MCPJ to volar MCPJ, wrapping around to include the elbow in flexion (90°). Wrist in intrinsic plus position.	Dorsal blocking	Flexor tendon injuries	30° flexion of wrist, 40–60 MCPs, IPJ in extension. Midforearm to entire digit.	
DIPJ, Distal interphalangeal joint; *IP,* interphalangeal; *IPJ,* interphalangeal joint; *MCP,* metacarpal phalangeal; *MCPJ,* metacarpal phalangeal joint.

the safest position is termed the *intrinsic plus* position: the wrist in 30 to 50 degrees of extension, MPJs in 70 degrees of flexion, and the IPJs extended (neutral) (see Table 119.4). This allows the intrinsic muscles to remain relaxed without tension because wrist flexion automatically causes the MPJs to extend, thereby placing the collateral ligaments in their shortest lengths. The affected extremity should be elevated to minimize edema. Establishing care with an occupational therapist who specializes in hand therapy has also been shown to improve outcomes, and even the most excellent of surgeries may be at risk for failure or patient dissatisfaction without therapy.[16] Adjunct measures for patient comfort—such as pain control, primarily with nonopioid medications unless bony work is involved; ice; rest; non–weight-bearing protocols; and lifting and work restrictions—can be crucial to the success of the repair and satisfaction of the patient.

TRAUMA

Emergency Control of Bleeding and Vascular Injuries

Control of bleeding is part of the ABCs of the primary Advanced Trauma Life Support (ATLS) survey—namely, the *C* for **C**irculation. Measures to stop the bleed, identify the source, and definitively manage should be undertaken. The Stop the Bleed campaign has been increasingly used to educate laypeople, first responders, and other trauma-associated personnel in the emergent control of bleeding extremities in the field, using direct pressure, elevation, packing, and a proximal tourniquet.[17] To avoid accidental injury to unharmed structures such as nearby nerves, placement of hemostatic devices, such as clips, blindly in the ED and nonspecific cautery should be avoided.

Critical examination is key in locating the source of bleeding. Even closed fracture may result in vascular injury, either by sharp mechanism of fracture lacerating the vessel internally or by traction mechanism.[18] If a tourniquet was applied in the field and there is question of vascular injury, examination should be performed with tourniquet down. Direct-pressure dressings should be applied and the hand elevated. Tourniquets should not be applied for any significant time before definitive repair in the operating room except in the setting of life-threatening hemorrhage.[18,19]

Life should be prioritized over limb, and one may have no fear of using sympathomimetic medications and their potential vasoconstricting effect to support blood pressure, even if free flap reconstruction or microvascular repair is planned or has been performed. Multiple studies have shown no increase in adverse events when pressors are used in conjunction with microsurgery, and norepinephrine is the preferred vasoconstrictor. In the case of severe extremity bleeding, the patient should be resuscitated according to ATLS and massive transfusion protocol guidelines.[20]

Lacerations, Fingertip Injuries, and Fingertip Amputations

Fingertip lacerations, crush injuries, and amputations are among the most common injuries. Effective initial management can make a difference between efficient return to function and complication. Careful physical examination and history are paramount to understanding what structures may be injured or exposed, without requiring a bedside "wound exploration," which could risk further damaging important structures. A complete neurovascular and musculoskeletal examination is performed. It is appropriate to consider certain procedures in the ED, including laceration repair with primary closure, nail bed repair, and revision amputation; however, if the area will necessitate formal flap coverage, the best results will be achieved in the operating room or procedure room.[21]

All patients who present with extremity injuries undergo radiography to rule out fracture or radiopaque foreign body. Any fracture with associated laceration or even puncture wound should be treated as an open fracture and administered antibiotics within 90 minutes of assessment as well as be thoroughly irrigated with at least 1 L of normal saline before closure. It is also important to consider tetanus booster if the patient is overdue or unsure of last vaccination and there was a contaminated mechanism of injury. Local anesthesia in the form of a digital block is usually sufficient for bedside treatment.[22]

A common injury pattern involves crush injury to fingertip, resulting in subungual hematoma and/or nail bed laceration. Fingernail anatomy can be appreciated in Fig. 119.17. These can

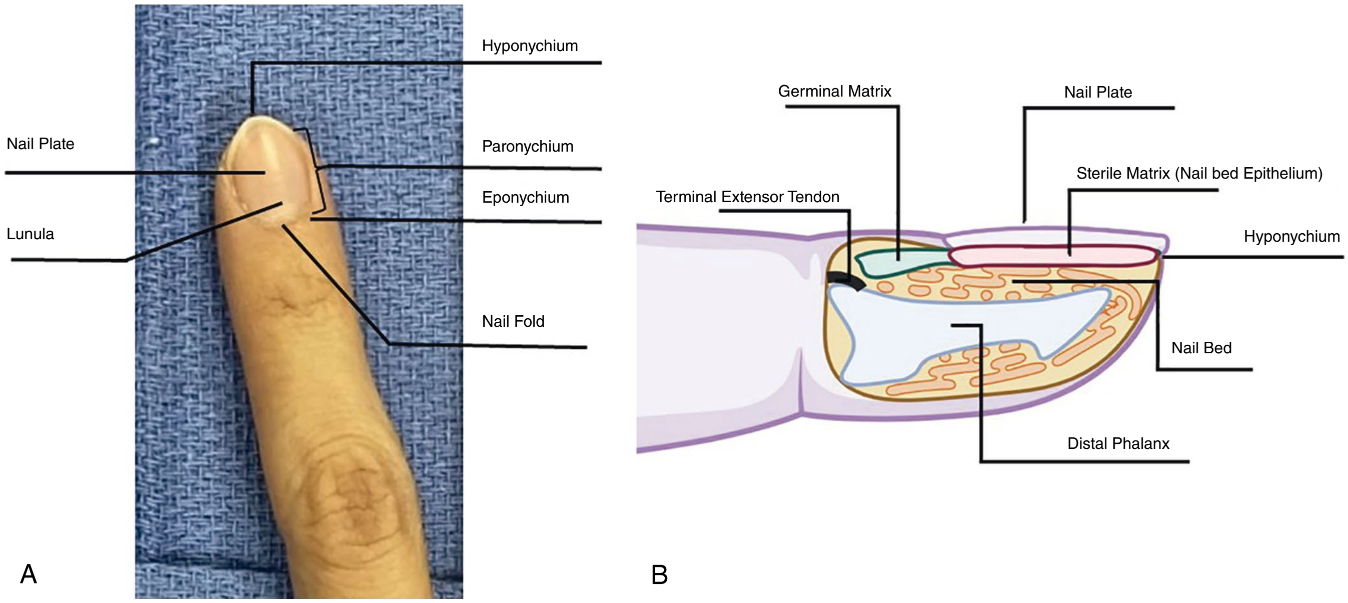

FIGURE 119.17 (A) Surface anatomy of the fingertip and fingernail. (B) Nail plate anatomy lateral view.

be very painful due to pressure buildup underneath the nail plate. If less than 50% of the nail is involved, pressure can be relieved using trephination with a large-bore needle or with an eye cautery device. If a greater portion of the nail plate is involved, one can consider removing the entire nail to evaluate and repair the injury. Both pediatric and adult nail plates can easily be removed with spreading of scissors beneath the plate (Fig. 119.18). Repair should be performed with 5-0 or 6-0 fast-absorbing or plain gut suture under loupe magnification (if available), and the cleaned native nail (if available) or a piece of suture foil should be inserted below the eponychial fold to act as a stent for the new nail to grow.[21] Nail bed repair is often sufficient to reduce a distal tip or complete tuft fracture.

Fingertip soft tissue injuries range from simple to complex. Applying the principles of the reconstructive ladder or elevator can be useful in determining procedures appropriate for the injury and the patient. If there is no or minimal exposed bone or tendon, fingertip wounds can be dressed to heal by secondary intention. The use of a semiocclusive dressing, changed weekly, can minimize patient discomfort and provide an appropriate moist environment for wound healing.[23,24] In children, using an amputated or avascular part as a composite graft is also an option (Fig. 119.19). Skin grafting alone, including split and full-thickness grafts, can be used; however, this should be avoided in the volar finger pulp because these are insensate and can contract. If bone is exposed and/or the soft tissue wound is larger, flap

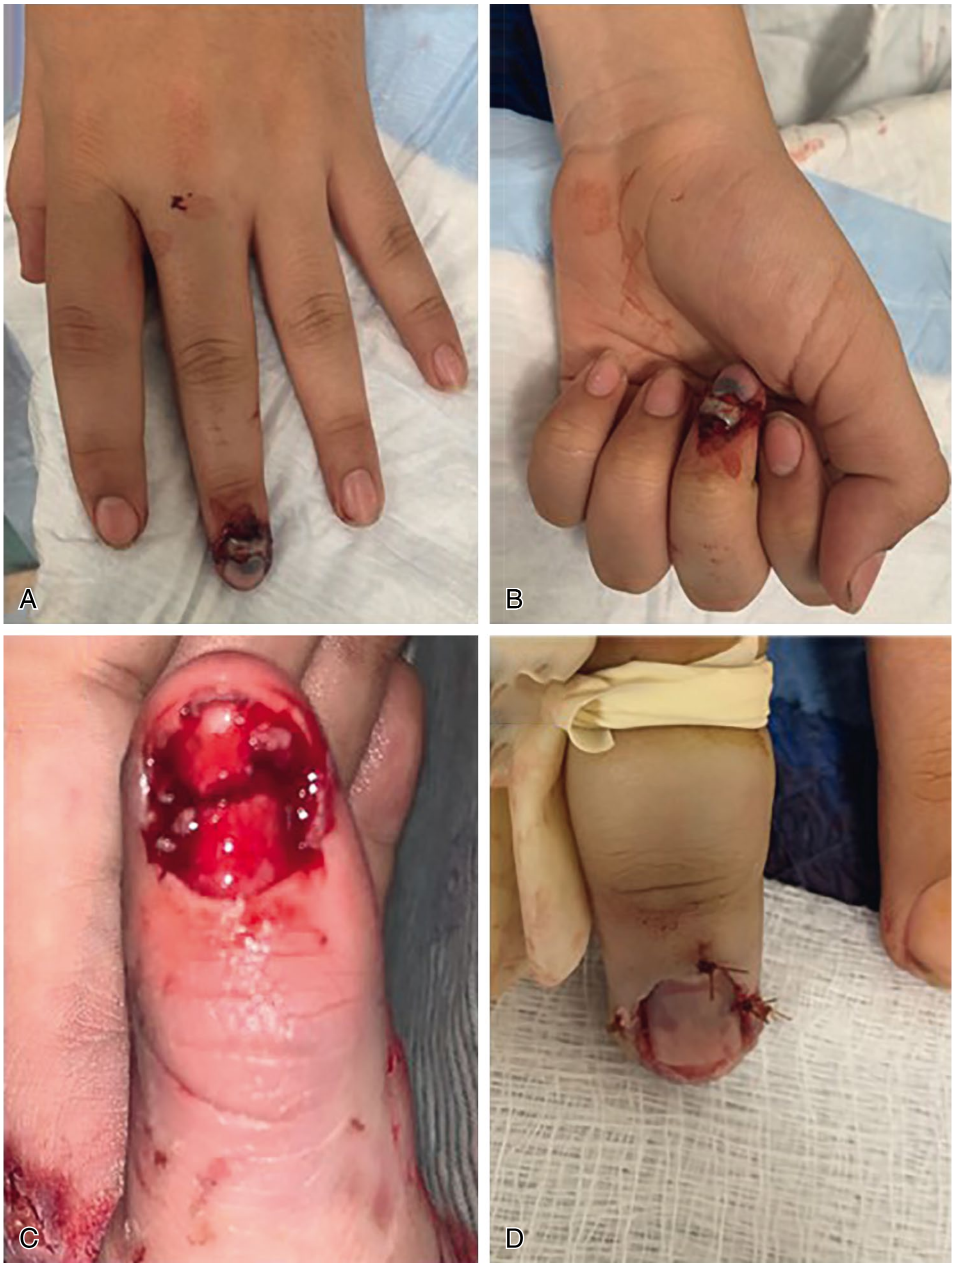

FIGURE 119.18 (A) Twelve-year-old patient with left middle finger crush injury with associated tuft fracture. (B) Examination revealed no tendon injury. (C) A different but representative patient with a sterile matrix laceration after nail plate removal. (D) After bedside repair with absorbable sutures and use of native nail plate as nail fold stent.

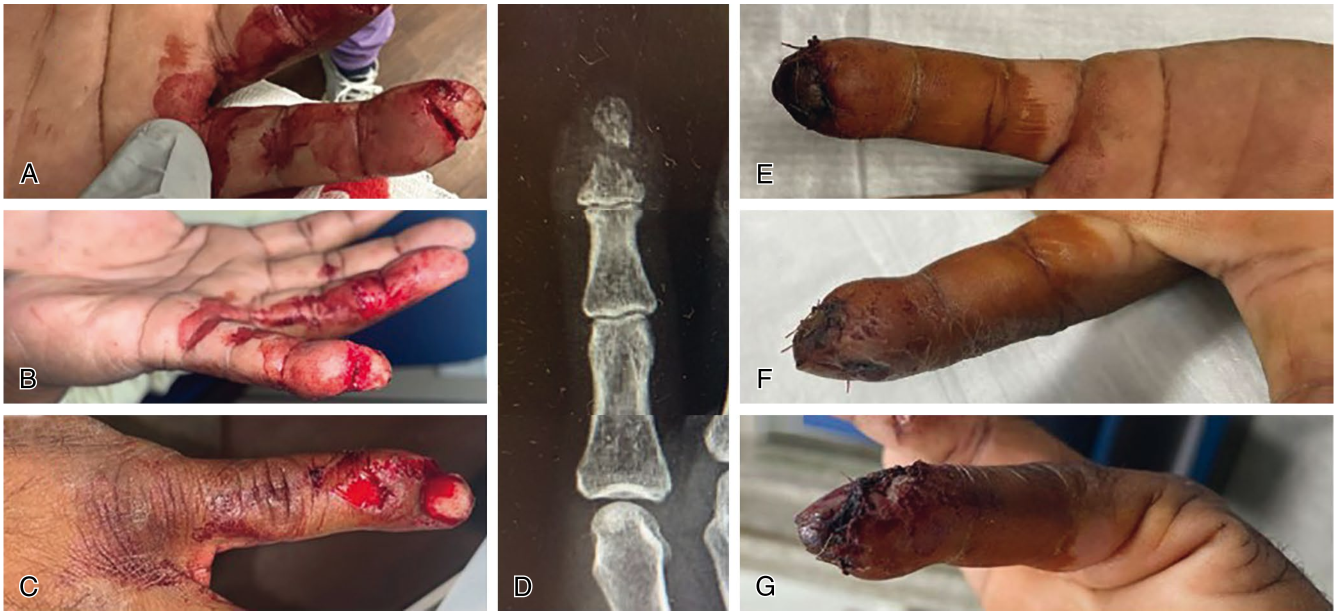

FIGURE 119.19 (A–G) Sixty-nine-year-old patient presenting with hatchet injury to left small finger resulting in near-complete amputation and transverse distal phalanx fracture. Patient did not desire replant; decision was made to use the dysvascular tip as a composite graft and repair laceration. One week postprocedure, there are some areas with healing; however, viability of fingertip is questionable, but digit remains out to length.

TABLE 119.5 Local Options for Flap Coverage of Finger Defects

FLAP NAME	COVERAGE OF…	DONOR SITE	BLOOD SUPPLY	FLAP TYPE/ MOVEMENT	PROS	CONS	FIGURE 20
Atasoy	Fingertip <1 cm	Distal volar pulp	Random pattern	V-Y advancement	Minimal donor morbidity, like with like	Small area of coverage, scar on volar pulp	A
Kutler	Fingertip <1 cm	Lateral fingertip	Random pattern	Bilateral V-Y advancement	Minimal donor morbidity, like with/ like	Small area of coverage, 2 flaps	B
Homodigital island	Middle → distal volar pulp	Same digit, skin around base of P1 and web space	Axial pattern—digital artery	Pedicled axial flap, proximal to distal	Full-thickness flap, excellent quality volar skin	Difficult dissection with nerve, long scar (tunnel of pedicle)	C
Thenar flap	Small or ring fingertip	Skin of thenar eminence	Random pattern	Delayed random pattern	Minimal donor morbidity, may be sensate	Recipient finger bent in position for 2–4 weeks, requires 2 surgeries	D
Moberg flap	Thumb tip	Volar thumb and thenar eminence	Bipedicle—thumb digital bundles	Axial advancement flap	Maintain as much length of thumb as possible, sensate, reliable	May have flexion contracture of thumb IP	E
Cross-finger flap	Middle or proximal phalanx volar skin	Dorsal skin/fascia of neighboring digit	Random pattern	Delayed random pattern	No sacrifice of volar skin, can cover large defects	Donor must be skin grafted, fingers must remain attached for 3–4 weeks (stiffness), 2 procedures	F
First dorsal metacarpal artery flap	Thumb volar surface	Skin over dorsal index finger (FDMA territory)	Axial- first dorsal metacarpal artery	Pedicle flap	Reliable, customizable based on defect	Dorsal skin (not volar), donor may require skin graft	G

FDMA, First dorsal metacarpal artery; *IP*, interphalangeal.

coverage can be considered if the patient desires maximum length retention of the digit or if the injured digit is the thumb (Table 119.5). Fingertips may be covered with advancement flaps, such as Atasoy or Kutler (Fig. 119.20A–B). Larger or oblique volar defects may require coverage with a cross-finger flap with skin grafting of the dorsal donor site, or dorsal defects may be covered with a reverse cross-finger flap and full-thickness skin graft.[25] Axillary pattern flaps, such as homo- or heterodigital island flaps, may be used with less donor site morbidity, or first dorsal metacarpal artery flap may be used for thumb, index finger, or web-space coverage. Moberg advancement flap is useful for volar soft tissue defects of the thumb to preserve as much length

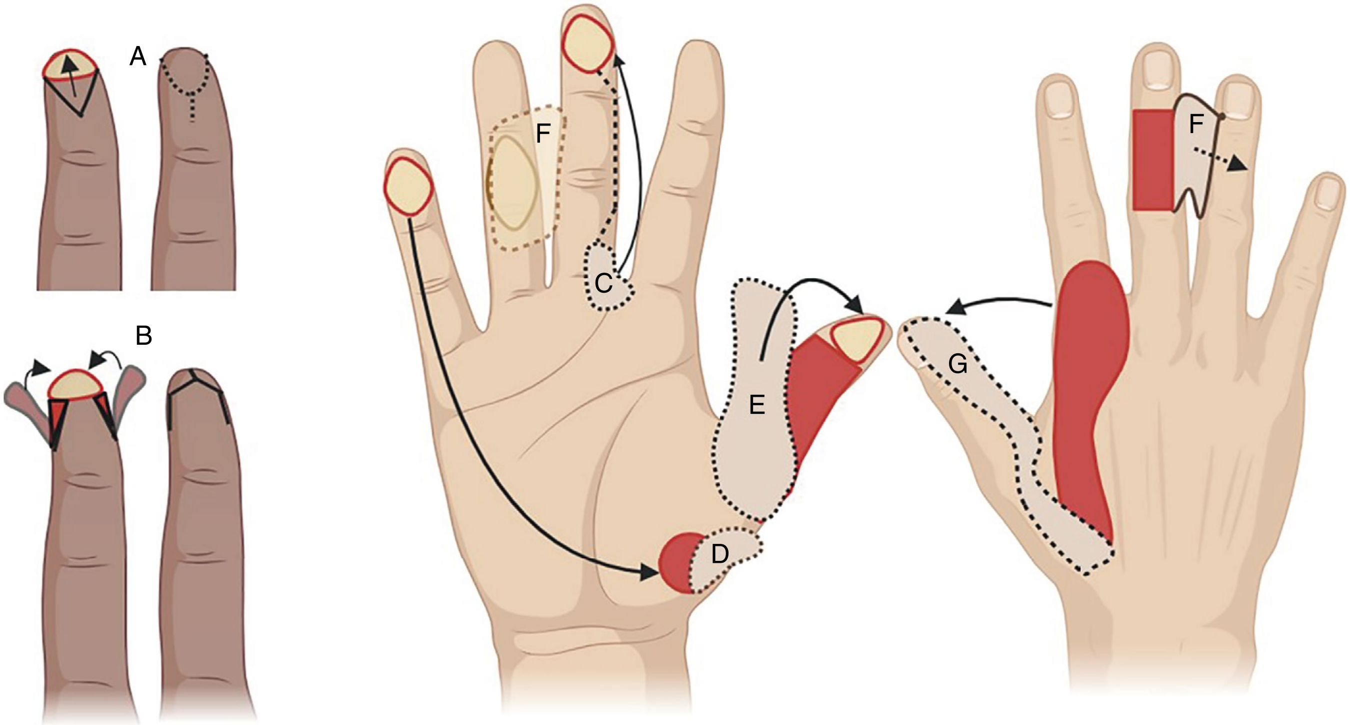

FIGURE 119.20 Local options for flap coverage of fingertip and other volar pulp defects. *A,* Atasoy flap; *B,* Kutler bilateral V-Y flaps; *C,* homodigital island flap; *D,* thenar flap; *E,* Moberg flap; *F,* cross-finger flap; *G,* first dorsal metacarpal artery flap. and therefore hand function as possible (see Fig. 119.20C–G). A thumb should never be primarily amputated at bedside unless traumatic amputation has already occurred.

If the fingertip has been slightly shortened by the trauma, the patient should be counseled that they may develop nail deformity if there is inadequate bony or soft tissue support, most commonly a hook deformity where the nail grows curved over the tip. If no coverage option is available or if the patient does not wish to undergo formal surgery, a revision of amputation with primary or secondary closure by trimming back exposed bone to obtain soft tissue coverage should be considered. If the injury is through the level of the lunula or proximal, the nail bed should be ablated by removing all sterile and germinal matrix (deep to the eponychial fold) to prevent horn nail deformity—small amounts of sharp nail plate protruding from the digit, which can be uncomfortable for the patient.[25]

Flexor Tendon Injuries

Flexor tendon function is very important to overall hand function, and injuries to this system have historically been complex due to the high force and balanced tension requirement.[26] The most common mechanism of flexor tendon injury is penetrating trauma or lacerations to the volar digits and hand.[15] Because of the volar position of the flexor tendons and proximity to the neurovascular bundle, there should be high suspicion of concomitant digital nerve or digital arterial injury. Visual inspection will reveal loss of flexion tone in the injured digit with resting position in extension and abnormal tenodesis.

Some general principles to adhere to for successful flexor tendon repair include adequate wound debridement, establishment of a solid multistrand core suture repair, and strict postoperative hand therapy regimen with early active range of motion when appropriate.[15] Repairs should have no gaps, and there should be minimal additional bulk to the repair, including knots or suture throws that would limit tendon excursion through the flexor synovial sheath.[27]

A tendon consists of longitudinally oriented bundles of collagen, and although it has great tensile strength when intact, it can be difficult to suture with conventional techniques because of material ripping or pulling through.[28] Most commonly accepted methods involve locking or grasping stitches that loop around multiple collagen strands in order to gain a strong anchor point.[15] The distance of suture bites should optimally be between 0.7 and 1.0 cm away from the cut end of the tendon to prevent fraying or suture slippage. Mechanical testing has shown that at least four core strands are required for an early active range-of-motion protocol, and up to eight core strands will have a stronger initial repair but may be technically challenging. Several methods for core sutures have been developed and widely used, which are shown in Fig. 119.21.[15] Knot placement should be either within the repair or away from the repaired edge to minimize catching within the pulley system. Appropriate suture selection, such as a braided nylon or polyester material, typically 3-0 caliber if the tendon will permit, will ensure that the suture itself is durable and minimally inflammatory while maintaining appropriate force for strong, active finger flexion.[29] The tendon should be handled atraumatically by minimizing the number of grabs with forceps; using sharp stabilization, such as a 25-g needle anchored through skin and sheath, rather than crushing the tendon with forceps; and sharply trimming back damaged edges with good, sharp tenotomy scissors. Not all partial lacerations require repair; however, if partial lacerations are visualized within the already created wound bed on initial ED evaluation, wound exploration and formal debridement should be considered.[28] Unrepaired edges may lead to fraying or

inflammation that causes nodule formation or triggering, or the partial laceration may propagate along the flexor tendon.

The patient and the situation should be considered in the decision for timing and type of tendon repair. Primary repair can be delayed up to 7 to 14 days because the tendon continues to receive nutrition from the synovial fluid and paratenon; however, there are certain injuries, such as zone 1 tendon avulsion, that result in disruption to the tendon blood supply, or vincula, and require more urgent repair. After 14 days, scarring and contracture of the tendons proximally may result in unacceptable levels of tension on the repair, and secondary repair with tendon grafting and/or multistage repair with silicone rod placement as spacers within the pulley system may be required for reconstruction.[15,30] Injuries with certain features, including extensive crush mechanism, loss of soft tissue coverage or pulley system, tendon loss of greater than 1 cm, or contaminated injuries, may not be candidates for primary repair. A failed or ruptured primary repair may be able to be re-repaired if diagnosed expeditiously. Patient factors and compliance are important to consider with this type of injury because postoperative therapy regimens can be very intensive. Patients who are unable to participate in therapy may develop painful contractures or tendon adhesions, which may compromise hand function without proper adherence to postoperative care.[16]

Flexor tendon injuries are divided into five zones (Fig. 119.22). In zones 1, 2, and 4, each tendon is surrounded by a synovial sheath and contained within a semirigid fibro-osseous canal, either the flexor tendon sheath of the digit or the carpal tunnel. In the zones 3 and 5, the flexor tendons are surrounded by loose areolar (paratenon) tissue. Tendon zones to the thumb are T1 through T3.

Zone 1 injuries occur distal to the insertion of FDS on the middle phalanx, so only FDP is injured. Closed avulsion injuries in this region are common and often termed *jersey finger* because the mechanism is often forced extension of the DIPJ in a flexed digit, such as occurs in sports if a player attempts to grab another's jersey. The primary blood supply in this region is tenuous and mainly derives from the vincula, thin connective tissue containing blood vessels that originate at the volar plates. If completely disrupted, this can lead to avascular necrosis of the tendon and result in suboptimal healing. The Leddy-Packer classification system for zone 1 flexor injuries lists four categories of injury, from most to least urgent (Table 119.6).[15] Sharp injuries can also occur in this zone and are not considered in this classification system.[31]

Repair of zone 1 injuries depends on the length of distal stump available. If there is greater than or equal to 1 cm, primary tendon coaptation with core sutures is a viable option; however, if there is less remaining at the insertion, core sutures will be unlikely to appropriately grasp/lock, and the tendon will need to be reinserted

TABLE 119.6 Leddy-Packer Classification System for Zone 1 Flexor Tendon Injuries

LEDDY-PACKER GRADE	LEVEL OF RETRACTION	VINCULA DISRUPTED?	BONE FRAGMENT?
1	Palm	Yes	No
2	A2 pulley	No	Small
3	A4 pulley or no retraction	No	Large
4	Palm	Yes	Large

into the distal phalanx.[32] This can be performed with suture anchors directly drilled into bone or using pull-through suture methods in which a core suture is placed into the tendon and the free suture ends are tied around the nail plate. Care should be taken to avoid placing sutures proximal to the lunula of the nail or through the germinal matrix because this can lead to nail deformity.

Zone 2 is demarcated by the insertion of FDS distally and the A1 pulley proximally and is also called Bunnel's "no man's land." In this anatomic zone, both FDS and FDP are susceptible to injury, and there are no strong attachments of the tendon to bone or vincula, often causing the proximal portion of the tendon to retract into the palm or even the wrist because of high levels of tension. If the tendon is not immediately present at the laceration site, Brunner or midaxial incisions should be used to extend the incision to the proximal extent of the pulley sheath as necessary for adequate exposure (Fig. 119.23).[15,33] Unless the end is clearly visible, the tendon should not be blindly grabbed through the sheath because this can cause unwanted trauma and increase the gap of usable tendon and increase inflammation postoperatively. Parts of the sheath may require incision or venting to locate a tendon remaining within the sheath system. The A1, A3, and A5 pulleys may be incised or excised as needed with minimal effect. The A2 and A4 pulleys should be left intact when possible to prevent tendon bowstringing; however, in cases when necessary, these can be incised in a "trap-door" fashion, vented, or even partially excised, with clinically negligible effects on tendon excursion.[34]

One pitfall of zone 2 is creating a strong and robust enough repair within the confines of a narrow sheath. In many cases, repair of the FDP alone will allow for a functional hand that will be able to achieve flexion at all digital joints; however, if FDS is present and easy to locate, repairing one or both slips may be advisable to prevent constant flexion forces on the DIPJ alone. Additionally, sutures and knots must be strong enough to handle a robust tendon but not overly bulky to create catching points on the annular pulleys.[35]

Finally, WALANT enables flexor tendon repair to be tested during the procedure.[10] Thus, one can determine intraoperatively that there is full flexor tendon excursion at the repair site.

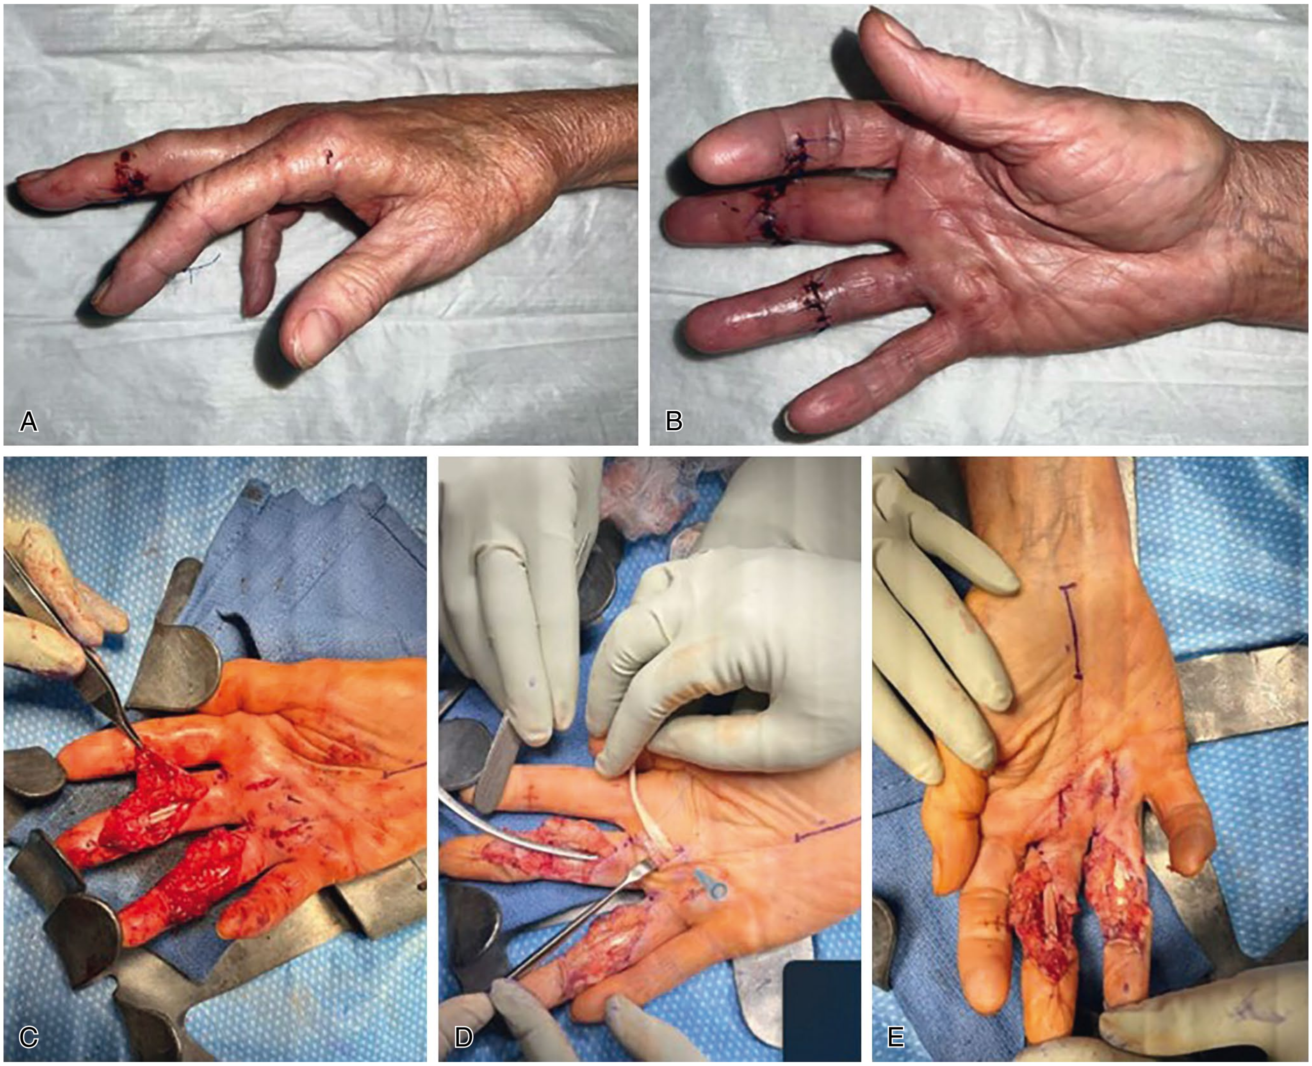

FIGURE 119.23 Zone 2 flexor tendon injury of middle and ring finger of right hand. Note the lack of resting flexion tone on examination (A–B). Patient underwent bedside laceration closure and operative exploration 5 days later, which revealed zone 2 flexor digitorum superficialis–only injury (C) with tendon retracted to the level of the palm (D) and tendon in situ after repair (E).

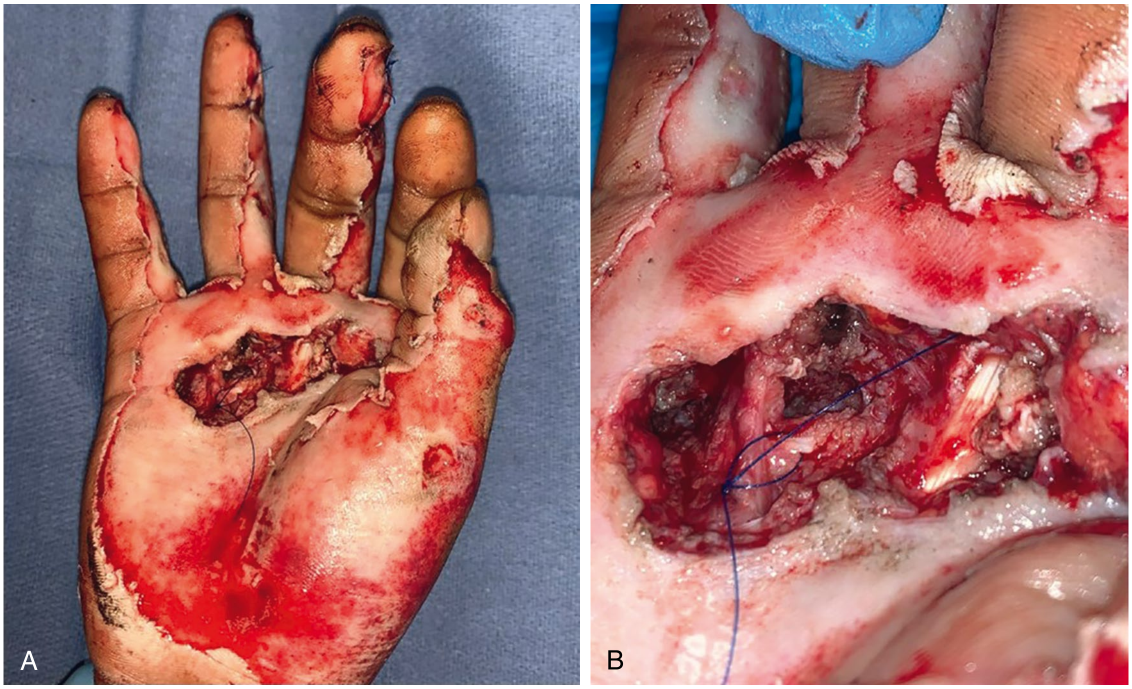

FIGURE 119.24 (A–B) Motorcycle collision resulting in extensive friction burns to the volar hand and soft tissue loss over flexor zone 3. Intraoperative examination revealed multiple-digit flexor digitorum superficialis and partial flexor digitorum profundus lacerations, nerve injuries to ulnar middle finger and radial/ulnar bundles of ring finger, and damage to common digital vessel to ring finger.

Zone 3 injuries occur in the palm and are typically not as prone to retraction as zone 2 injuries.[33] There is no synovial sheath at this level, and one must be wary of the superficial palmar arch (Fig. 119.24). In zone 4, or the carpal tunnel, there are nine tendons plus the median nerve and radial artery that are running through a small space, and multiple structures may be lacerated. Knowledge of anatomy is important, and the tendons typically lie in the configuration of FDS to ring and middle fingers volar to small and index, respectively, FDP linearly along the carpal bones, and FPL in a separate bursa radial to the median nerve. In zone V, flexor muscle bellies may be involved, and multiple figure-of-eight sutures will be required to repair the muscles in order to prevent ripping the sutures through. This zone has a poor prognosis due to muscle fibrosis and scarring, which limits flexor function and excursion.

Extensor Tendon Injuries

The extensor tendons have a complicated insertion distally, with multiple slips and expansions forming the extensor hood.[1] This allows intricate and independent extension of each joint while other joints are in various degrees of flexion; however, it also makes the tendons susceptible to closed and open injury because of their superficial position and thin nature distally. The extensor tendon system is divided into nine zones of injury from distal to proximal, where odd numbers overlie joints starting at the DIPJ and even numbers correspond to injuries over long bones (Fig. 119.25).[36] Extensor tendons are more amenable to bedside repair because they are unlikely to retract and require less tensile strength than flexors. It is important to understand the anatomy in each zone of injury because it will allow identification of the damaged structures as well as choice of proper suture and repair technique.[37] The more distal zones 1 to 3 over the

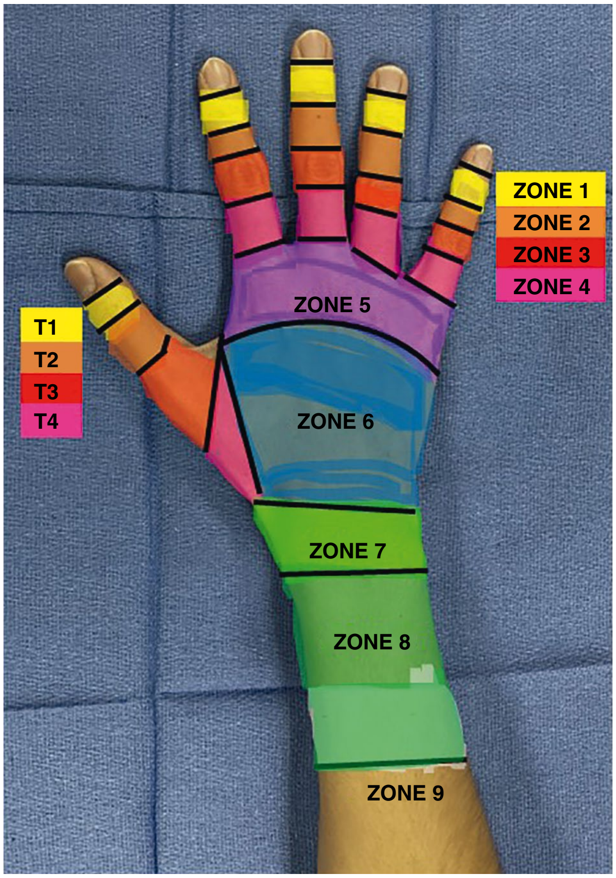

FIGURE 119.25 Zones of extensor tendon injury.

fingers are usually too thin to attempt core suture repair, and a figure-of-eight, running, or cross-stitch repair is usually sufficient, whereas more proximally, the tendons become thicker and are thus able to accommodate two- to four-core strand repairs. As a general principle, open injuries should be treated with thorough washout, debridement, and prompt administration of antibiotics. All lacerations of 50% of the tendon or more should be repaired to minimize risk of propagation of the injury and restore function; <50% may be treated conservatively and allowed early active motion.

Zone 1 injuries are termed *mallet finger* and are injuries to the terminal tendon insertion at the DIPJ. They most commonly result from closed injuries in which rapid forced DIPJ flexion occurs against resistance, such as "snagging" the finger on an item. Open injuries with lacerations or crush injuries may occur, and mallet fractures can occur with a bony avulsion fragment being pulled proximally by the retained terminal tendon (Fig. 119.26). Closed injuries may be treated with either 6 weeks of DIPJ splinting in extension or with Kirschner wire (K-wire) fixation of the DIPJ in extension, based on patient preference.[36] Bony mallets with volar subluxation or >50% of joint surface involved in fragment should be treated operatively with bony fixation. Complete avulsion of the terminal tendon may require suture anchoring to the distal phalanx or tendon grafting, transfer, and/or reconstruction if there is significant soft tissue loss. Chronic mallet fingers that are untreated can result in a swan-neck deformity, in which the DIPJ is flexed and the PIPJ is hyperextended.

Zone 2 injuries most often occur as a result of sharp lacerations and have the potential to injure the underlying triangular ligament or the lateral bands (or both). These should be washed out and repaired with running or finger trap pattern sutures. Static splinting is recommended in addition to local wound care for associated laceration.

Injuries to zone 3 occur over the PIPJ and cause disruption of the central slip and possibly the lateral bands of the extensor tendon, which extends the PIPJ. Central slip injury can be evaluated using Elson's test (see Video 119.5). A typical mechanism of closed injury is blunt trauma to the dorsal digit or dislocation of the PIPJ. Unrepaired zone 3 injuries will result in a boutonnière deformity, in which the PIPJ will be unable to extend and therefore flexed, whereas the DIPJ is hyperextended due to maintained and tightened insertion of the terminal tendon, lateral bands, and oblique retinacular ligament.[37,38] Closed, acute injuries may be treated with a trial of splinting the PIPJ in extension, with aggressive passive DIPJ stretching exercises to prevent hyperextension and allow the intact attachments to relax. Subacute injuries (e.g., lacerations closed without diagnosis of tendon injury) typically require surgical exploration and tendon repair if there is residual extensor lag.[39] Zone 3 injuries in the thumb may involve the EPL, EPB, or both. EPL is important to assess with the tabletop test, in which the patient is instructed to lift the thumb straight up off a flat surface with the IPJ extended. Isolated EPB injury may not require repair because EPL can compensate. Core sutures of 4-0 Prolene may be able to be placed at this level.[36]

Over the proximal phalanx in zone 4, the extensor tendons are more robust and typically thick enough to accommodate a 4-0 Prolene core suture. These injuries are typically related to proximal

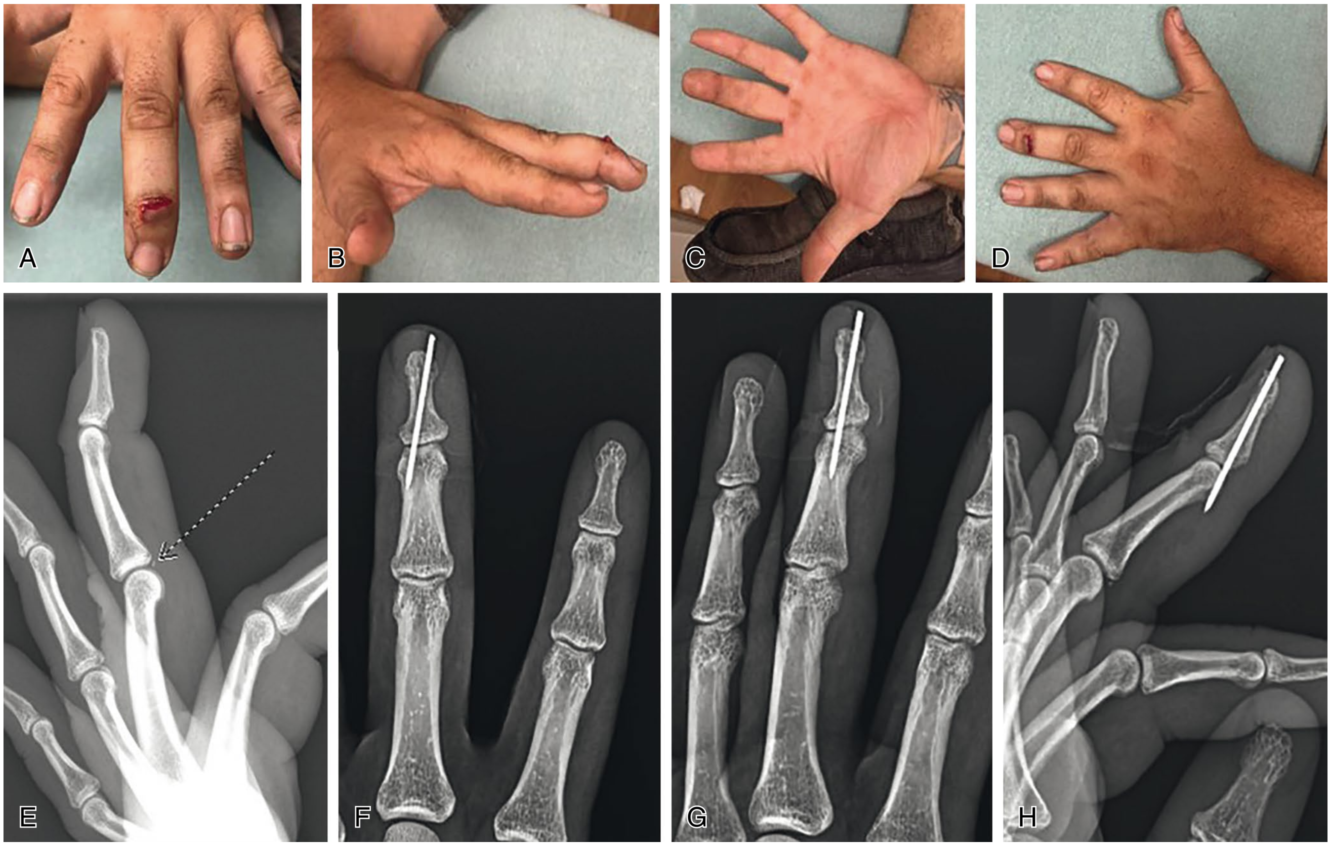

FIGURE 119.26 Laceration over left middle finger distal interphalangeal joint resulting in open zone 1 extensor laceration (A–D). Associated volar base of distal phalanx avulsion fracture without flexor injury (E). Patient underwent extension pinning for 6 weeks (F–H).

phalanx fractures, and many are partial lacerations that may not require repair. If repair is required, patients should be started on early active range-of-motion protocols.[38]

Zone 5 injuries occur over the MCPJ, and a common cause of injury is a human bite from a closed fist punch to the mouth. These injuries are always contaminated and typically involve the joint, so it is imperative to thoroughly irrigate and administer antibiotics. At this level, vulnerable structures include the main body of the extensor tendons as well as the sagittal bands, which are thin ligamentous structures that hold the tendon centrally over the base of the proximal phalanx and head of the metacarpal, then loop around the bones to insert on the volar plate. Injury to these structures may result in subluxation of the tendon during flexion, typically in the ulnar direction. Clean injuries can be repaired immediately (Fig. 119.27); however, contaminated or "fight bite" injuries should be left open or loosely approximated over Penrose to allow any infection to clear. Tendon repair or repair of the sagittal bands can occur in a delayed fashion.[36]

Sharp trauma to the dorsum of the hand may result in zone 6 extensor injury. At this level, strong juncturae tendinum between the individual tendons prevents retraction and may even present with preserved function, especially in the ring and middle fingers. These injuries usually have a favorable prognosis and are easy to access and repair with 3-0 caliber core sutures. Early active range of motion or range-of-motion splinting may be employed after repair.

Injuries to the wrist, zone 7, can be complex, similar to zone 4 flexor tendon injuries. All of the finger extensors, thumb extensors, and wrist extensors may be involved in the injury, and anatomic matching is important when multiple structures are involved. At this level, the tendons may retract through the extensor retinaculum, and counterincisions in the forearm may be required to retrieve the proximal stump. These should be repaired with 3-0 core sutures and 5-0 epitendinous suture, and treatment will involve splinting in mild extension with transition to early active motion.[36]

Zone 8 and 9 injuries are proximal enough to involve the musculotendinous junction and muscle bellies in the distal and proximal forearm, respectively. These often have suboptimal outcomes because of the difficulty of anchoring to the muscle fibers, and if muscle is ischemic or denervated, these may require tendon transfers at a later date to restore function.[36]

Nerve Injuries

Nerve injuries can be devastating for upper extremity function, and it takes an astute clinician to recognize patterns of nerve injury and enact proper diagnosis and management. The Sunderland and MacKinnon classification,[40,41] the most widely used classification, describes six types of nerve injury: neurapraxia (grade I), axonotmesis (grades II to IV), and neurotmesis (grade V) (Table 119.7). Neurapraxia can be thought of as a myelin-only injury, in which there is inhibited conduction without anatomic destruction of nerve fibers. This might occur with a closed injury with associated traction, such as a fracture or dislocation, or as an iatrogenic injury via surgical retraction or prolonged tourniquet use. Most patients can expect a full recovery, but it may take up to 3 to 4 months. Grade II injuries result in discontinuity at the level of the endoneurium. Grade III injuries result in axonotmesis with greater damage to the surrounding membranes, and Grade IV injuries result in complete disruption of all axonal structures within an intact endoneurium only. These types of injuries have less favorable prognoses and may result in neuroma in continuity if axons become disoriented. Grade V injuries are complete disruptions of the nerve (neurotmesis) by transection or avulsion injury.[40] MacKinnon described grade VI injuries as involving multiple grades of injury within the same area of the nerve.[41]

Nerves initially regenerate at the rapid rate of 1 mm per day; however, after initial healing, there may be variable rates in progression depending on the perineural environment, patient factors such as age or blood-flow–limiting comorbidities, or inhibiting fibrosis or other scar formation.[42,43] Initially, nerve injury will result in motor weakness, paresthesias, and decreased sympathetic functions. Notation of a loss of sympathetic tone (dryness, lack of pilomotor response) or color change in a nonvascular pattern, paresthesias and loss of sensation, and motor deficits on strength testing are important for documentation and must be carefully teased out from other factors, such as fracture or dislocations causing movement limited by pain, tendon injury, or vascular injury. Nerve conduction studies are not immediately helpful but become valuable 3 weeks after injury, when fibrillation and denervation potentials can be measured. Nerve conduction studies can also be useful in measuring level of reinnervation and monitoring progress of reinnervation.[44]

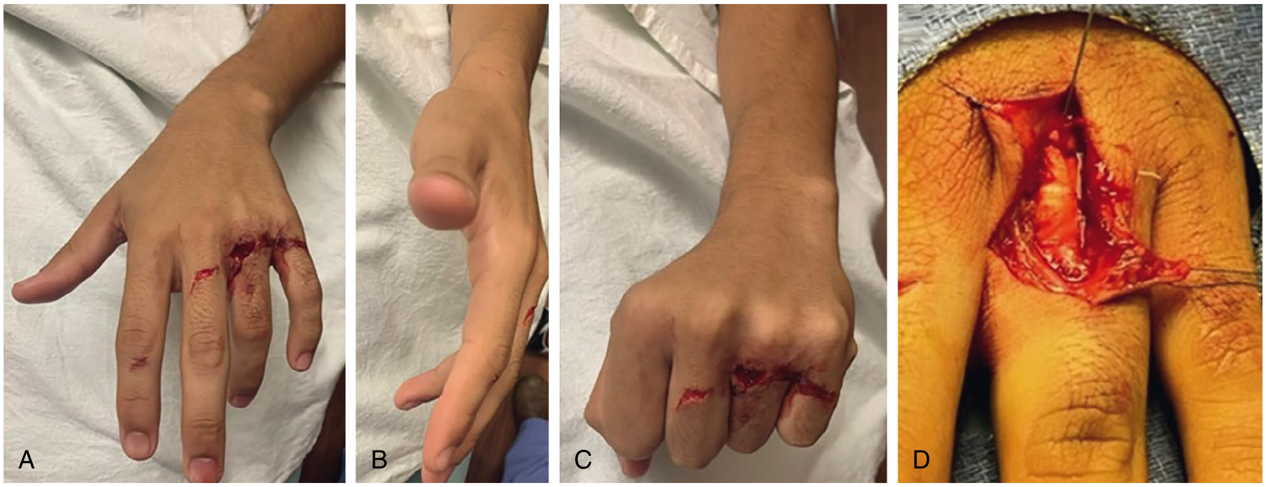

FIGURE 119.27 (A–C) Laceration over the ring finger metacarpophalangeal joint (MCPJ) with associated extensor lag of ring finger at MCPJ. (D) Patient underwent bedside wound exploration and repair of zone 5 complete extensor laceration.

TABLE 119.7 **Sunderland MacKinnon Classification System**

SUNDERLAND GRADE	SEDDON CLASS	STRUCTURES INJURED	WALLERIAN DEGENERATION?	TREATMENT
I	Neurapraxia	Segmental Demyelination	No	Typically spontaneous recovery
II	Axonotmesis	Axon injured with preserved endoneurium, perineurium, epineurium	Yes	Often recovers spontaneously, prolonged time period
III	Axonotmesis	Axon and endoneurium injured, intact perineurium and epineurium	Yes	Unlikely to recover, may require surgery
IV	Axonotmesis	Axon, endoneurium, perineurium injured, only epineurium remains in tact	Yes	No spontaneous recovery, likely to form neuroma in continuity, requires excision + grafting
V	Neurotmesis	Nerve completely transected	Yes	No chance of recovery without surgery for reapproximation
VI	Mixed nerve injury	Mixed picture, more typical with crush or compression injuries	Some	Requires close clinical and EMG or NCV monitoring to guide decisions

EMG, Electromyography; *NCV,* nerve conduction velocity.

Primary nerve repair should be undertaken in a controlled, nonemergent manner and does not need to occur on the day of injury unless there are other emergent reasons to operate. Primary repair can be performed within 72 hours; however, if clinical examination is confounding, evidence reports good outcomes up to 3 weeks after injury, which allows time for some edema to resolve and other concomitant injuries to stabilize. Delayed primary repair at 1 to 6 months can be accomplished with relatively high expectations of return to clinical function, which can be useful to allow grades II to IV injuries to fully declare their extent before surgical intervention.[43] It is important to consider the window of timing repair in the context of end-organ atrophy, especially motor neurons. Repairs between 9 and 18 months show markedly less regeneration compared with earlier repairs, and repairs after 18 months generally are only performed for sensation or pain management because target muscles have often become atrophic and fibrotic beyond repair.

Primary nerve repair is the preferred technique because of superior outcomes in return of function if this can be accomplished.[45] It is recommended in sharp injuries with minimal contamination. Techniques for optimization of repair include mobilization of cut ends so that there is no tension on the repair because tension will lead to dehiscence or traction-type injury. Nerve gaps >1 cm typically cannot be mobilized enough to be repaired primarily.[46] The proximal and distal ends should be sharply debrided back to healthy-appearing fascicles using only very sharp instruments. Nerve ends should be handled without trauma and favor forceps grasping the epineurium rather than fascicles to avoid crush injury.[45] Using magnification, epineural suturing with 8-0 to 10-0 (depending on nerve caliber) for fascicle realignment and nerve approximation remains the most effective method of repair per the literature.[47] Fibrin glue has been used to augment repair. Nerve cuffs or nerve wraps theoretically prevent exposure of escaping axons from the site of repair and may help lower the suture burden; however, they have not been definitively demonstrated to provide superior outcomes.[48]

Injuries resulting in soft tissue and nerve loss will not be able to be repaired primarily. In these cases, nerve autograft remains the gold standard for reconstruction.[45,49,50] Most common donors include sensory-only peripheral nerves, such as the sural in the leg for large-diameter nerves, or terminal sensory branches encountered in the upper extremity within the same wound, such as the PIN innervating the wrist joint. Bioabsorbable nerve conduits and cadaver nerve allografts can be used in place of autograft to reconstruct defects, most commonly up to 2 cm in the literature. Both are acellular but form a directional matrix thought to both harbor directional neurotrophic factors and provide a directing scaffold for regenerating axons. Commercially available polyglycolic acid tubes, bovine collagen scaffolds, and decellularized human nerve allografts are all acceptable options, and the literature has not shown superiority of any individual material for reconstruction of small peripheral nerves with appropriate size matching.[45,49–52]

Fractures and Dislocations

Pain, swelling, limited motion, ecchymosis, and deformities suggest the presence of a fracture or dislocation. Plain radiographs (AP, oblique, lateral) should be done as part of the primary examination. Some intraarticular fractures may require advanced imaging, such as CT without contrast.[3] Postreduction films should be obtained in the splint or cast to evaluate quality and stability of reduction.

Standard language is used to describe fractures. Classification includes displaced versus nondisplaced. Nondisplaced fractures are in anatomic alignment and do not require reduction but may still require immobilization in order to prevent deformation. Fractures may also be angulated, rotated, or comminuted. Comminuted fractures result in more than two fragments. Angulation is described by the direction in which the apex of the fracture is pointing, and displacement is described by the direction of the distal fragment.[53] Fractures are also described by their pattern; they may be transverse, longitudinal, oblique, or spiral. Fractures may also occur intraarticularly, or within the joint capsule, or extraarticularly. Fractures may be open or closed, depending on whether a wound that communicates with the fracture is involved. Open fractures should be irrigated and debrided in an urgent manner. Antibiotics should be administered within 90 minutes of identification of any open fracture to minimize risk of osteomyelitis or nonunion.[54] A dislocation is described according to the direction of displacement of the distal bone in the involved joint, and a fracture dislocation involves a fracture fragment intraarticularly in addition to the dislocation.

Displaced fractures or dislocations are repositioned as soon as possible to decrease soft tissue injury, decompress nerves that might be stretched, and relieve kinking of blood vessels. Fractures may have stable patterns, in which displaced fractures or dislocations are repositioned as soon as possible, or may be unstable, in which bedside reduction, despite the best attempts, will be unlikely to result in improvement without fixation.[53] Indications for surgery include

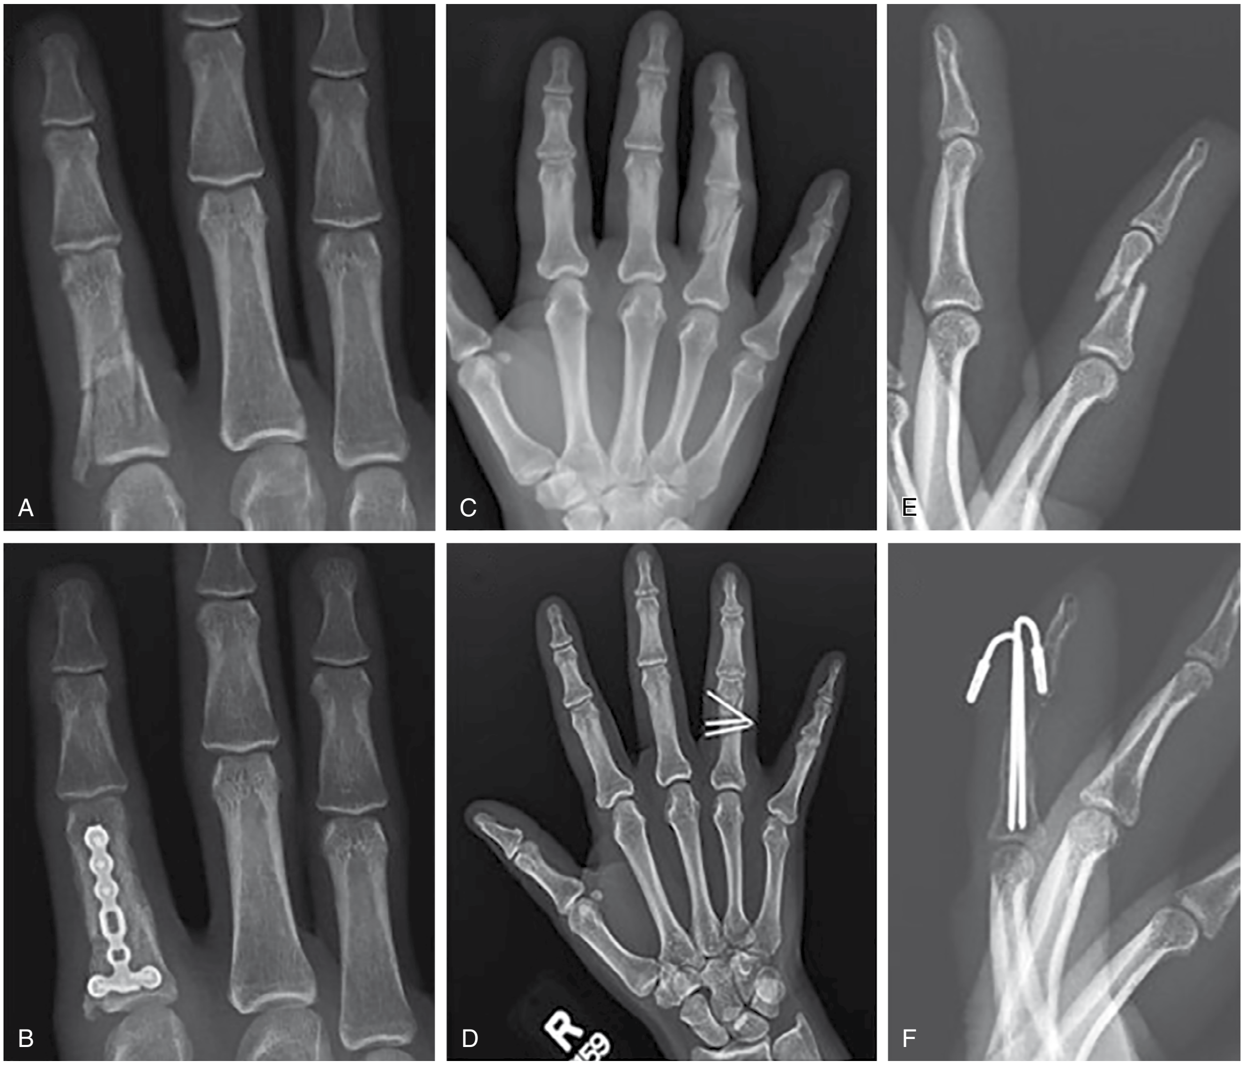

FIGURE 119.28 Methods of middle and proximal phalanx fracture fixation. Comminuted intraarticular fracture of index finger proximal phalanx, fixation with open reduction, and placement of permanent T-plate (A–B). Long oblique fracture of ring finger proximal phalanx treated with transverse Kirschner wires (K-wires) (C–D). Short oblique dorsally displaced fracture of small finger middle phalanx with intramedullary K-wire fixation (E–F).

inability to obtain and maintain acceptable reduction, open fractures, or significant bone loss that requires bone grafting.

Bone healing occurs either by primary or secondary mechanisms. In primary bone healing, rigid and stable fixation must be present for coapted bone edge to heal by direct matrix repair and osteogenesis. In secondary bone healing, micromotion is allowed by immobilization or K-wires, and callous matrix is laid down, which later undergoes enchondral ossification.[53,55] Desire for rigid, anatomic internal fixation must be balanced by postoperative concerns for stiffness or contracture formation. In the fingers, especially, tight anatomic space, multitude of important longitudinal structures, and need for disruption of important soft tissue landmarks for placement of plates or screws may cause more burden, including adhesion or scar formation, tendon attrition or rupture, or unforgiving stiffness at the IPJs. Thus, less invasive methods such as splinting, buddy taping, or K-wire fixation may be more appropriate and result in superior functional outcomes despite a less anatomic-appearing healed fracture or even a functional malunion.[55,56] Patient factors, such as level of demand of lifestyle and expected participation in therapy, can also be factored into selection of fixation method and/or nonoperative management.

Middle Phalanx and Proximal Phalanx Fractures

Distal phalanx fractures are covered in the fingertip injuries section, but briefly, tuft or tip fracture is typically comminuted and usually reduced by nail plate splinting. Avulsion injuries can also occur, as discussed in the flexor and extensor tendon injuries sections. Middle and proximal phalanx fractures are common from both athletic and industry mechanisms. Fractures of the phalangeal head or base are intraarticular and may involve the condyles or insertion of the collateral ligaments. Shaft fractures of the middle phalanx are likely to be volarly angulated if distal to the FDS insertion and dorsally angulated if proximal to the FDS insertion. Proximal phalanx shaft fractures tend to displace with dorsal angulation due to the insertion of the interosseous muscles at the base.[53]

Nondisplaced and minimally displaced fractures may be treated as noninvasively as possible with buddy taping or a short course of immobilization. If clinically significant malrotation or angulation is present, percutaneous methods such as K-wire fixation or headless compression screws can be used to minimize soft tissue disruption and tendon adhesions (Fig. 119.28). For comminuted or intraarticular fractures, open reduction internal fixation (ORIF) may be required. There are plating systems tailored to dorsal, volar, and midaxial approaches, without consensus on the best approach (see Fig. 119.28A–B).[57–61]

Metacarpal Fractures

Metacarpal fractures are common and result from mechanisms such as axial force to the metacarpal head (a punch to a solid object), direct blow to the hand, or torquing or rotational forces on the hand.[53] Fractures of the metacarpal can occur at the head, neck, shaft, or base. Border digits are more often injured due to prominence. The CMCJs of the fingers have varying degrees of freedom, with significant movement at the small finger and increasing rigidity more radially, resulting in more tolerance for fracture displacement or angulation in the small and ring fingers than the middle or index.

Fractures of the head are rare but involve the articular surface of the MCPJ and should be treated operatively if there is >25% of joint surface involved or step-off >1 mm. Metacarpal neck fractures are very common, especially in the small and ring fingers, and are termed *boxer's fractures.* These fractures usually have dorsal apex angulation with volar displacement and shortening of the metacarpal head. These fractures in the small and ring fingers are usually treated nonoperatively, and even angulation up to 70 degrees may be well tolerated. Index and middle fingers, however, can tolerate only 10 to 20 degrees of dorsal angulation.[62] A typical closed reduction maneuver is called the *Jahss maneuver,* in which the IPJs are flexed 90 degrees and upward pressure is applied to the metacarpal head while volarly directed pressure is applied to the area of fracture itself. Shaft fractures are typically classified by morphology, including transverse, oblique (short or long), and longitudinal or comminuted. Shaft fractures have a similar morphology to neck fracture; however, oblique or spiral fractures are unlikely to be stabilized by closed reduction. Base fractures may involve CMCJ dislocation or may be intraarticular, requiring fixation.

Many metacarpal fractures can be treated nonoperatively with short immobilization or buddy taping.[56] General indications for operation include malrotation, angulation, or intraarticular displacement. Percutaneous insertion of K-wires (Fig. 119.29A–B), in multiple configurations, has been shown to be successful.[57] Intramedullary screws and nails (see Fig. 119.29C–D) have become increasingly popular because of minimal soft tissue dissection and

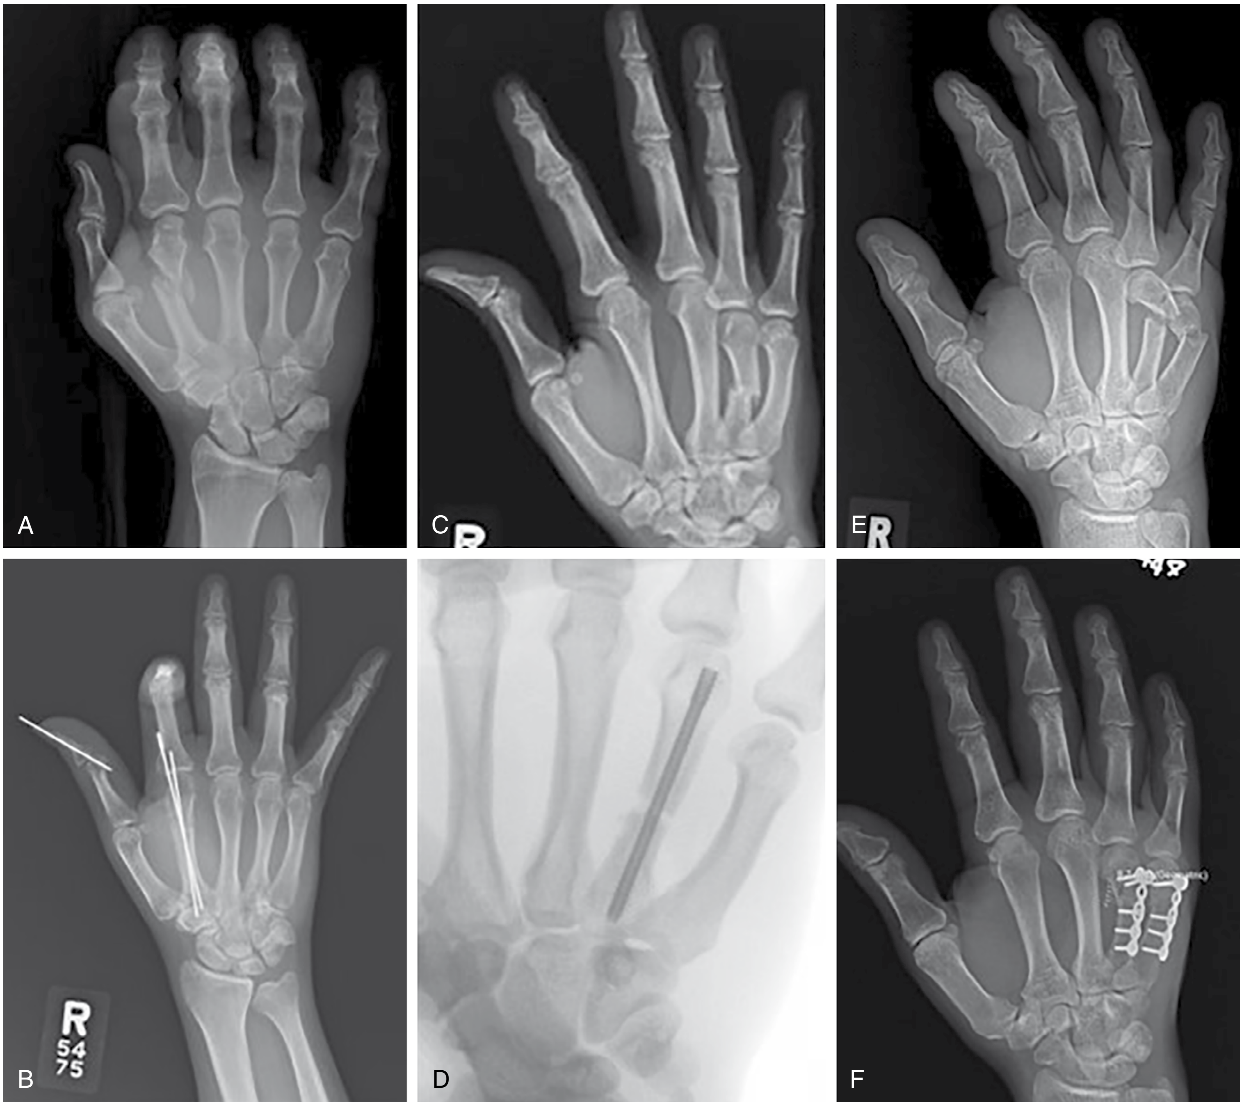

FIGURE 119.29 Various methods of metacarpal fracture fixation. Fixation of a comminuted index finger neck fracture with Kirschner wires (A–B), transverse ring finger shaft fracture compressed with intramedullary nail (C–D), and small and ring finger angulated neck fractures reduced with T-plates and bicortical screws (E–F).

earlier return to work.[55] Lag compression screws are particularly useful for long oblique fractures and provide appropriate support to the fragments with less hardware burden. Comminuted fractures may require a bridging construct, which can be placed via dorsal approach to minimize damage to vital neurovascular structures (Fig. 119.29E–F).[63] Because of their large size relative to the phalanges, plate and screw fixation can be technically less demanding.

The thumb metacarpal shows some differences in fracture patterns. Fractures of the metacarpal head and neck are very rare, whereas fractures of the shaft and extraarticular base fractures are typically amenable to closed reduction and nonoperative techniques because of their stable, typically transverse nature. These should be immobilized with a thumb spica splint in an abducted position to prevent first web-space contracture.

Intraarticular fractures of the thumb metacarpal base can be classified into two-fragment, oblique intraarticular fractures, or Bennet fractures (Fig. 119.30),[64] and comminuted fractures, or Rolando fractures. The anatomy of the fracture causes a classic displacement pattern of dorsal, proximal, and radial due to the pull of still-attached APL to the major fracture fragment. Bennet fractures are difficult to treat with closed reduction and typically respond better to operative intervention. This can be

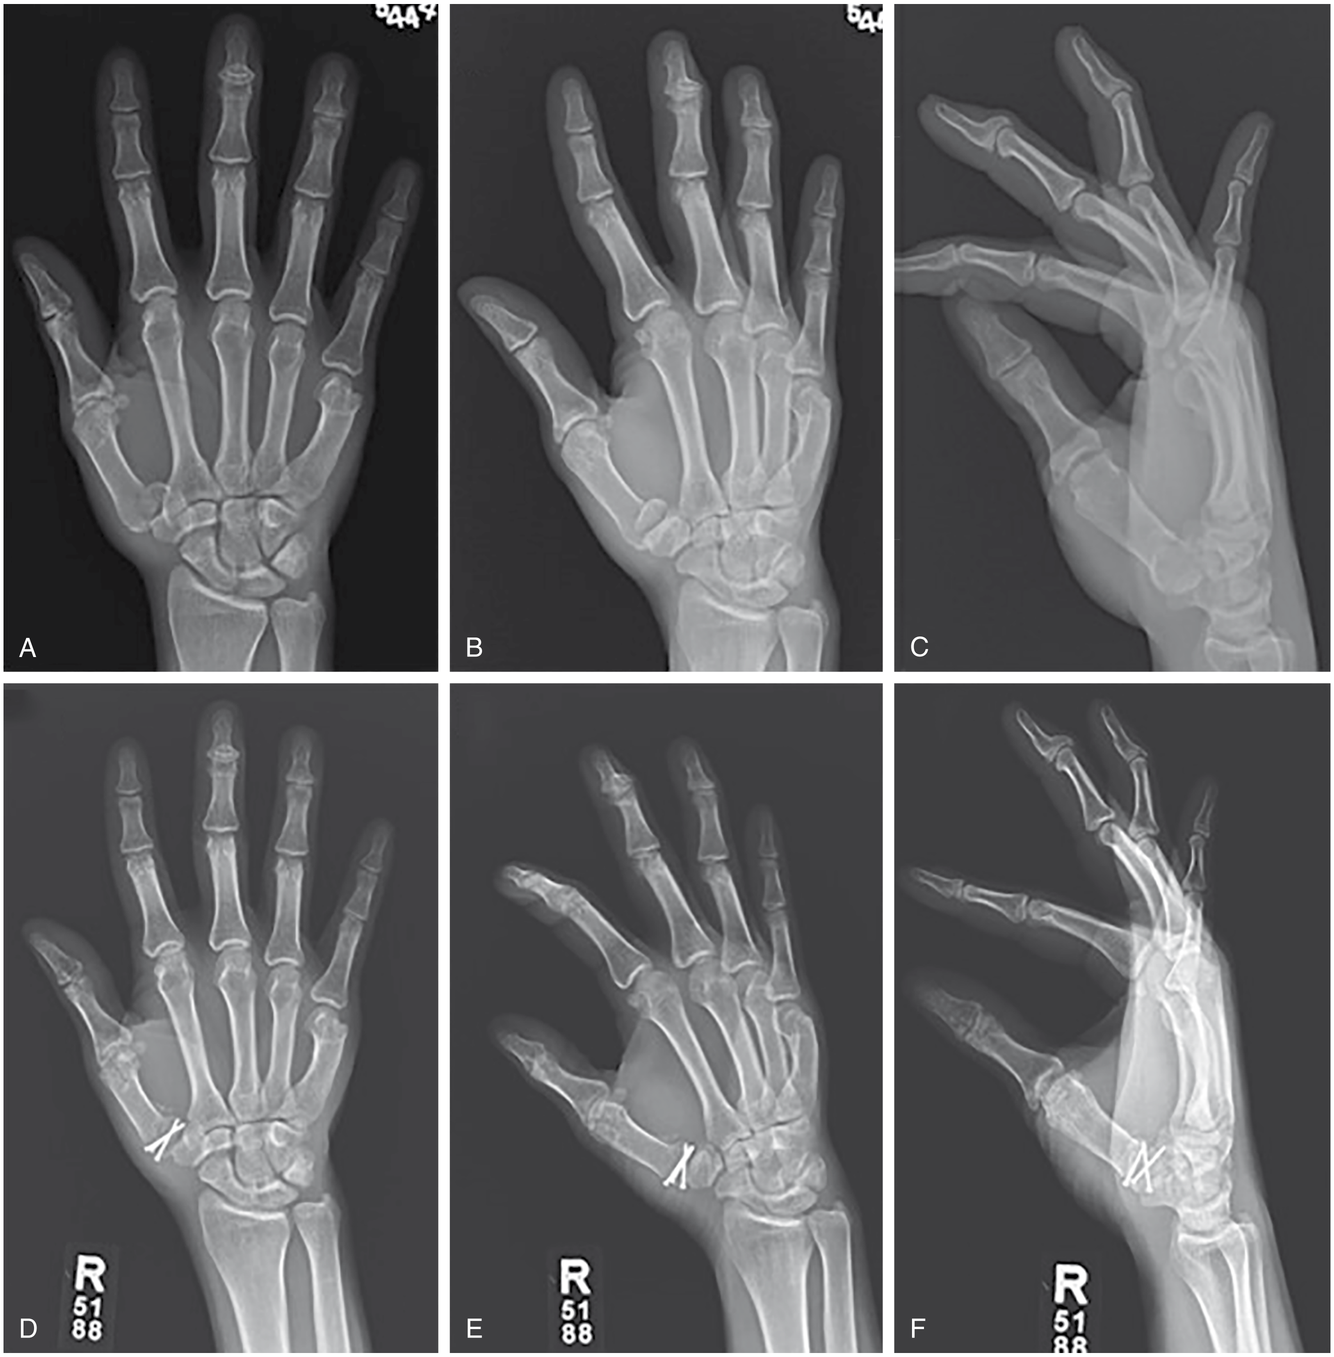

FIGURE 119.30 (A–F) Thumb base metacarpal intraarticular two-fragment fracture (Bennet fracture) with classic displacement of the larger fragment proximally and supinated. Fixation with open reduction and lag compression screws.

accomplished with K-wires or open reduction with plates or screws if necessary. Rolando fractures are typically difficult to treat in a closed manner and often have poor outcomes despite attempts at multiple K-wire pinning or plating.[53,63] An external fixator that includes the index metacarpal or open reduction with fragment pinning can provide good outcomes for the patient. If anatomic reduction fails or pain persists, thumb CMC arthrodesis can be performed as a salvage procedure.[63]

Carpal Bone Fractures

Carpal bone fractures can lead to wrist instability or alteration of wrist biomechanics. The scaphoid is the most fractured carpal bone and accounts for approximately 60% to 70% of all carpal injuries. Examination will show tenderness within the anatomic snuffbox or tubercle. In addition to a standard wrist series, a scaphoid view with the wrist in full ulnar deviation and 20 degrees extension should be obtained. Only 25% of nondisplaced acute scaphoid fractures are seen on plain radiographs. Advanced imaging, such as CT or MRI, should be considered, and studies have shown that CT and MRI may have equivocal sensitivity and specificity. Early diagnosis is essential to expeditiously provide the appropriate treatment and limit complications.

Treatment of identified or suspected nondisplaced scaphoid fracture should include immediate immobilization in short arm, thumb spica cast. The scaphoid has greater than average healing times compared with other fracture sites because of its tenuous, retrograde blood supply, so 12 to 14 weeks is standard for immobilization.

Displaced scaphoid fractures should be treated with ORIF to minimize risk of nonunion and encourage faster healing and return to work, typically with headless compression screws (Fig. 119.31). A large percentage of the scaphoid surface is covered with articular cartilage, making plate fixation difficult. Complications of scaphoid fractures are common, including malunion and nonunion rates between 10% and 20% for nonsurgically treated fractures, with more proximal being higher risk. Nonunion can result in arthritis, wrist pain, or instability and may progress to scaphoid nonunion advance collapse (SNAC) wrist.

The triquetrum is the second most common fracture. It is typically a small avulsion fragment. Most triquetral fractures can be treated nonoperatively with immobilization for 10 to 12 weeks in an ulnar-based splint. Trapezium fractures may result in combination with distal radius or thumb metacarpal fractures and can be treated with compression screw or K-wires if unstable to preserve the thumb CMC saddle. Capitate and lunate fractures are rare because of their protected nature in the center of the carpus. Hook-of-hamate fractures can occur with a direct blow to the palm, such as with a golf club or tennis racket, and if causing persistent pain, they should be treated with hook-of-hamate excision.

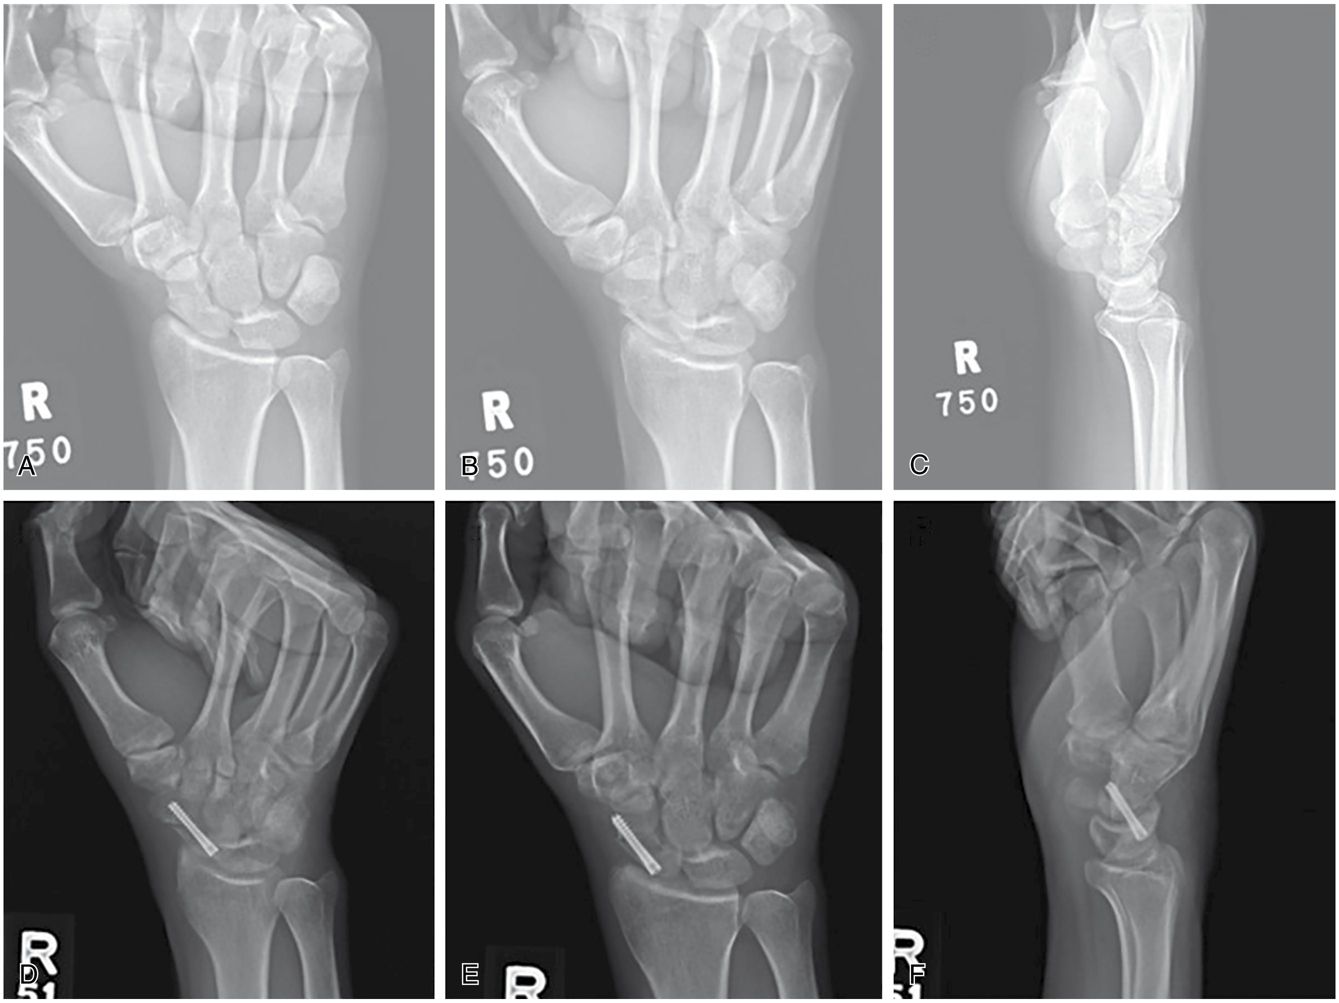

FIGURE 119.31 (A–F) Clenched-fist view with scaphoid midwaist fracture with ulnar displacement and impaction. After fixation with percutaneously placed headless fixation screw.

Fractures in Children

The Salter-Harris classification[65] describes five types of epiphyseal injuries, the most common type of which is a type II injury through the epiphysis and including the diaphysis (Table 119.8). Any fracture that damages the growth plate can result in length discrepancies and thus should be followed longitudinally to ensure anticipated growth is occurring. Fixation should be performed with the growth plate in mind, with greater use of K-wires and smooth pins rather than threaded screws, which may result in growth arrest. Younger children may not be cooperative with immobilization and may require bulkier splinting and casting, whereas in adults buddy taping would be sufficient.

TABLE 119.8 Salter-Harris Classification for Epiphyseal Fractures

CLASS	INJURY RELATIVE TO PHYSIS	PROGNOSIS	DIAGRAM
I	"Slip" injury through the physis	Excellent, usually treated nonoperatively	II	Injury to physis and metaphysis, "above" the physis	Excellent, usually treated with immobilization; most common type	III	Injury to physis and epiphysis, "lower" than physis	May require operative intervention	IV	Injury through metaphysis and epiphysis, "through"	Requires operative intervention, prone to limb length discrepancy	V	Crush injury of the physis	Poor prognosis, prone to limb-length discrepancy	
Dislocations and Ligamentous Injuries

Dislocations and fracture-dislocations can occur at any of the finger and wrist joints, from the DIPJ to the wrist. Recognition of partial versus complete ligament injuries as well as joint stability on examination and x-ray can determine whether closed reduction is likely to be successful or if operative exploration is indicated.

Dislocations are frequently seen at the PIPJ. Dislocations are commonly reported in the volar, dorsal, and lateral directions. Dorsal dislocations are most commonly a result of axial force to the tip of the digit. After reduction, joint stability is assessed, ranging through active and passive examiner-directed range of motion with moderate stress application to confirm there is no redislocation. Buddy taping for dislocations with stable active motion can be more effective than immobilization for regaining a normal range of motion.[60,66]

MCPJs have a much stronger ligamentous "box," with attachments of the transverse metacarpal ligament, the sagittal bands of the extensor system as secondary support, and the addition of broader fibrous collateral ligaments. Dorsal dislocations are more common in the border digits. This can occur as a subluxation, which is amenable to closed reduction; however, complete dislocations are often not able to be reduced. The volar plate, flexor tendons, A1 pulley, or even lumbricals may become interposed within the fracture site, requiring open reduction. The CMCJs can also be dislocated as a result of mechanisms with high axial load, such as fall on outstretched hand, and usually dislocate in a dorsal direction.[66]

The thumb has slightly different anatomy because of the greater degrees of freedom of the MPJ that allow for thumb opposition. A more common pattern of injury is forced thumb abduction and hyperextension from a sudden radially directed force. This may sprain or tear the ulnar collateral ligament. Laxity at the thumb IPJ should be assessed with a varus/valgus stress test; marked laxity of more than 40 degrees indicates a complete rupture or grade III ligament injury (Fig. 119.32). Acute ligament tear can cause development of a Stener lesion, specifically the interposition of the thumb adductor aponeurosis between the base of the proximal phalanx and the insertion of the ligament. This is commonly seen in skiers falling with the ski pole in hand and a thumb abduction injury. Ligament repair or reconstruction is required; suture anchor methods, direct repair, and even arthroscopic repairs have been described.[66]

Replantation, Revascularization, and Amputations

Replantation is a complex undertaking involving multiple components of soft tissue and skeletal reattachment and, most importantly, microvascular anastomosis. It is important to have a discussion regarding success rates, recovery time, and expected function. Not every patient or situation is an appropriate candidate for a replantation[19]; some scenarios with historically poor outcomes include the following:

- Severe crush or multilevel injury of the amputated part, especially with multiple levels of compromised vasculature
- Patients with uncontrolled psychosis, especially if the part was self-amputated

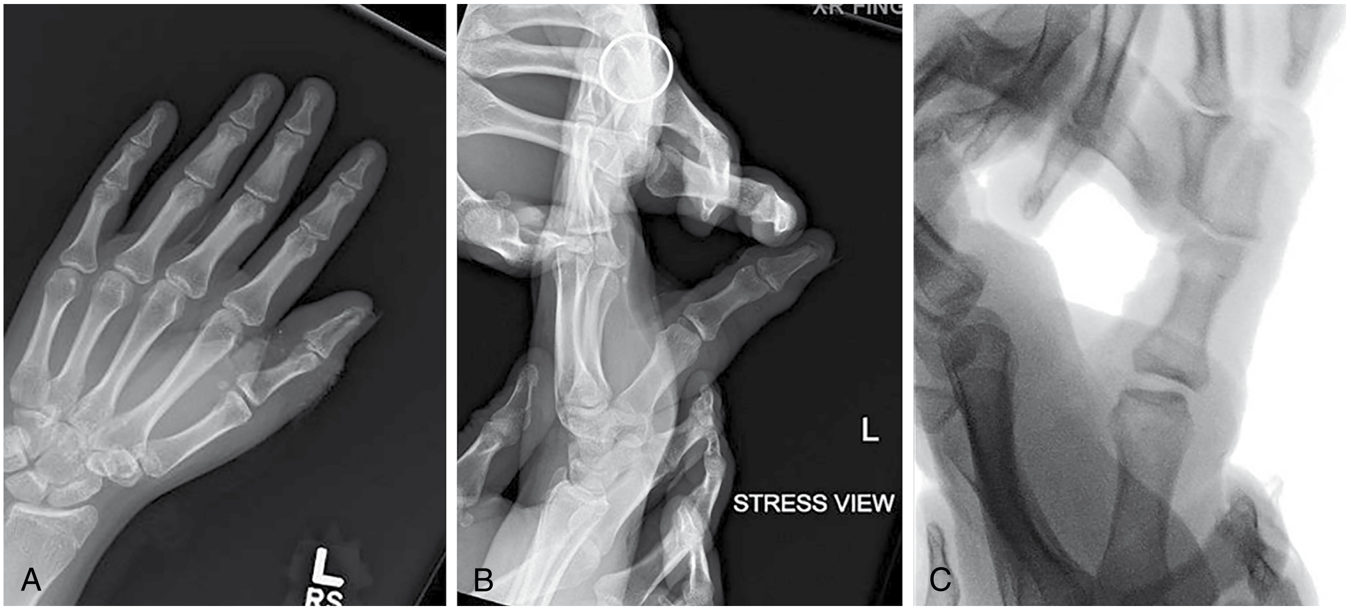

FIGURE 119.32 (A) Patient presented with left thumb metacarpophalangeal joint pain with no acute fracture. (B) Stress view reveals laxity of the ulnar collateral ligament without defined end point. (C) Intraoperative fluoroscopy after ulnar collateral ligament repair shows stabilization with firm end point on stress.

- Amputation of a single digit proximal to the FDS distal insertion (zone 2), except the thumb
- Patients with blood vessels not amenable to microvascular re-anastomosis

Indications for replantation of amputated parts are as follows:

- Whenever possible, for a thumb amputation (it provides >40% of the overall hand function)
- Single digits that have been amputated distal to the FDS insertion
- Multiple injured digits
- Most amputations in children, including single-digit amputations
- Guillotine-sharp clean amputations at the hand, wrist, or distal forearm

Replantation is the reattachment of the part that has been completely amputated, whereas revascularization requires reconstruction of vessels in a limb that has been severely injured or incompletely severed, even if this is only a "skin bridge." Revascularization has more favorable outcomes because venous and lymphatic drainage may be intact.[25]

The mechanism of injury is important in determining the viability of replantation or revascularization. Guillotine amputations, or sharp, clean cuts, are the most favorable. They allow for primary repair of all structures with minimal soft tissue loss and a smaller zone of injury. Crush or avulsion amputations are less favorable. They typically involve comminuted fractures and multilevel or wider zones of injury. They may require vessel resection and vein grafting and cause vessel thrombosis as a result of intimal damage.[67]

Ischemia time is also an important consideration when evaluating a patient for replantation. For amputated digits, ischemia time is better tolerated, with reports of good outcomes hours after over 24 hours of cold ischemia time. Major amputations containing a larger muscle bulk can only tolerate 4 to 6 hours of ischemia, and the parts often cannot be properly stored or cooled to prolong time to repair. Proper storage of the amputated part includes wrapping in saline-moistened gauze or towel, sealing in a plastic bag, and placing the bag inside an ice water slurry. Direct placement of ice can result in ice crystal formation and tissue damage.[19]

Amputation can always be considered an alternative when replantation or revascularization is contraindicated. The stump is preserved with as much length as possible in most cases, except where the residual part can inhibit function or limit prosthetic wear, such as short residual proximal phalanx or wrist disarticulation. Nerve ends are cut sharply and allowed to retract into the soft tissue in the hopes of limiting neuroma formation. Primary targeted muscle reinnervation (TMR) may also be considered. A formal ray amputation can be performed on an elective basis for a more cosmetic or functional result (Fig. 119.33).

Operative sequence of replantation has been standardized. The distal amputated part is examined under a microscope to sterilize and tag nerves, arteries, and veins by a separate surgical team. With significant soft tissue loss, bone shortening may be considered but should not compromise joint function. Skeletal fixation is performed first to stabilize the digit, then tendon/muscle repair. Afterward, arterial inflow is reestablished, with possible vein grafts, followed by veins and the nerves. For major replantation, the order differs in that vascular inflow should be established first in a temporary or permanent manner to minimize ischemia time. Circulation may be established using a carotid shunt or catheter between the cut arterial ends.[47] Topical 2% lidocaine and papaverine may help with vasospasm.

Postoperative course is critical in the first 72 hours after microvascular repair. These injuries should be managed with loose dressings, elevation, immobilization, and digit checks for color, turgor, capillary refill, and Doppler signal. The room should remain warm, with judicious use of anticoagulants and no use of nicotine. Venous congestion is usually the most common complication, and this can be managed in multiple ways, such as with leeches, removal of the nail bed and controlled bleeding with heparin-soaked pledgets, or manual pinprick with topical heparin because the digit will not be sensate.[68] Trials have shown that the use of loading-dose

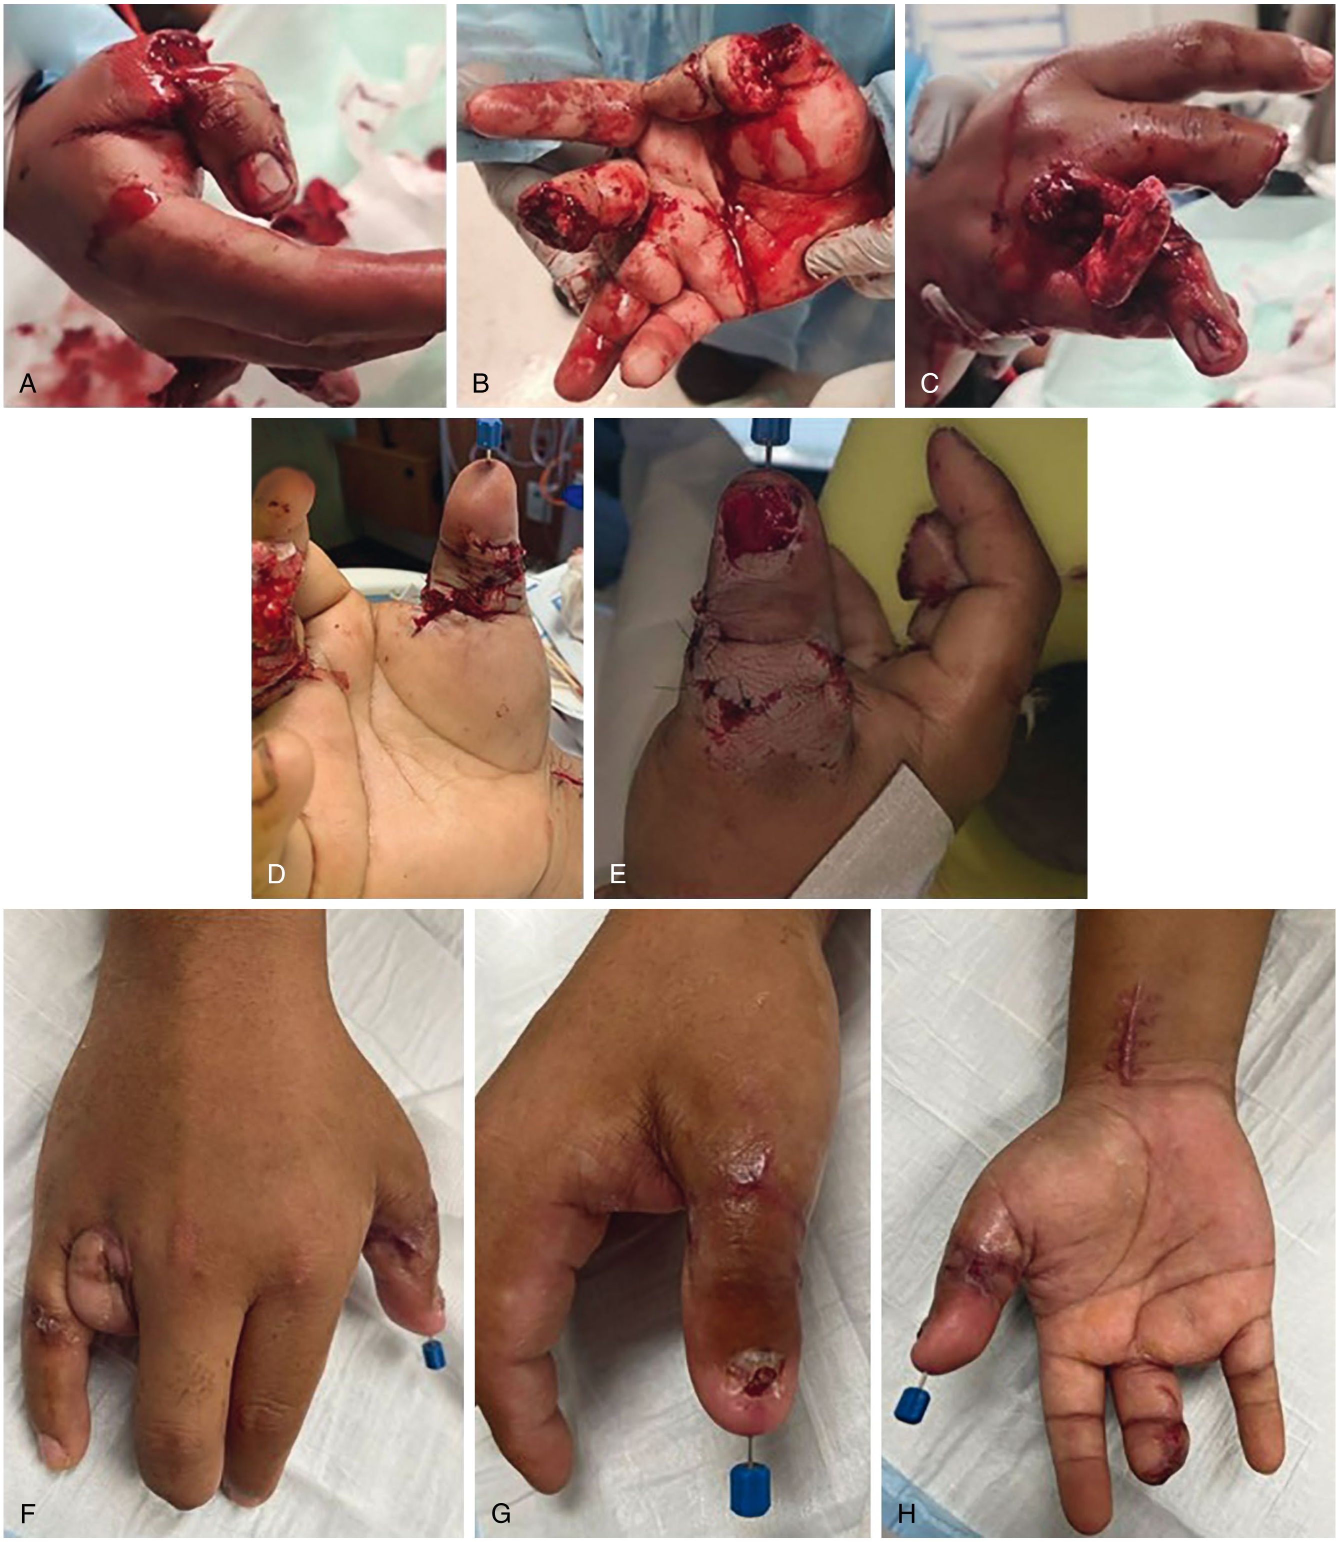

FIGURE 119.33 (A–C) Near amputation of the thumb, amputation of the long finger, and crush injury to ring finger after table saw injury. Patient underwent thumb replantation, middle finger revision amputation, and ring finger disarticulation with fillet flap for dorsal web-space coverage. (D–E) Early postoperative course showed venous congestion; thumb nail plate was removed, and heparin-soaked gauze was applied, with resolution of congestion. (F–H) Six weeks postoperatively, patient shows signs of good soft tissue healing; pin was removed from the thumb during this visit.

aspirin followed by low-maintenance dose is sufficient for prevention of arterial thrombosis (see Fig. 119.33D–E).

Approach to the Mangled Extremity

Mangling injuries to the upper extremity are complex problems that often involve multiple levels of tissue injury, including bone, muscle, tendon, soft tissue, and neurovascular structures (Fig. 119.34). Compounding tissue damage and loss, these injuries often occur as a result of unfavorable mechanisms of injury, such as crush, degloving, or avulsion, and can occur in highly contaminated environments.[69] Mangling injuries are unique to each patient and require a multidisciplinary approach, with goals in mind for optimal function.[70,71]

Upper extremity mangling injuries are often obvious on primary survey; however, care should focus on ATLS protocol and prioritize life over limb because forces that cause upper extremity crush or blast injuries may be sufficient to cause other organ damage as well.[18] It may be necessary to use pressure or tourniquet methods to stop hemorrhage to prevent substantial blood loss leading to hypovolemic shock.[17,20] Attempts should be made to stabilize the limb injury until it can be addressed.

Perfusion should be the first focus of repair effort. Muscle and some soft tissue elements will tolerate only 4 to 6 hours of warm ischemia, and longer times may result in massive cell death and compromise functional recovery.[19] Vascular anastomosis without skeletal stability would result in tenuous repair with the risk of avulsion during surgical maneuvering. In cases of prolonged ischemia time, bleeding of the extremity ~200 cc before reestablishing circuit connection can reduce toxic metabolites entering circulation and causing heart, liver, and kidney damage.

Thorough debridement of contaminated and devitalized tissue is critical to achieving limb salvage and preventing infection. This removes embedded foreign material and nonviable tissue. Prompt administration of antibiotics, typically including a cephalosporin and, in “dirty” injuries, the addition of an aminoglycoside within 90 minutes of presentation, has been shown to reduce morbidity and mortality. Washout of open fractures should occur on first exploration.[54] Clearly devitalized tissue may be removed, which may require multiple debridements. Negative-pressure wound therapy has been shown to be safe and result in decreased edema and lower infection rates, and it can be used as a bridge to soft tissue coverage or in conjunction with repair to improve healing.[72]

Once vascular inflow has been established, skeletal fixation should be performed, if possible, with weight-bearing spanning plates, or external fixation in the case of severe comminution. Regarding the hand, the thumb provides 40% of hand function, and efforts should be taken to maintain as much length as possible and prioritize replantation if that is an option. In multiple-digit injuries, other important digits include the middle finger, which will take over the key pinch part of grasping, as well as the small finger, which is important for power grasp. Primary amputation may be required if the patient has other life-threatening injuries or mangling beyond salvage efforts, although care should be taken to preserve as much limb length as possible in the initial surgery to maximize future prosthesis fitting. An occupational prosthesis may afford greater function than a stiff, nonfunctional hand.

Timing of soft tissue coverage can range from immediate to subacute, although prolonged exposure of vital structures results in suboptimal outcomes due to development of collagen fibrosis and chronic wound contamination (Fig. 119.35). With advances

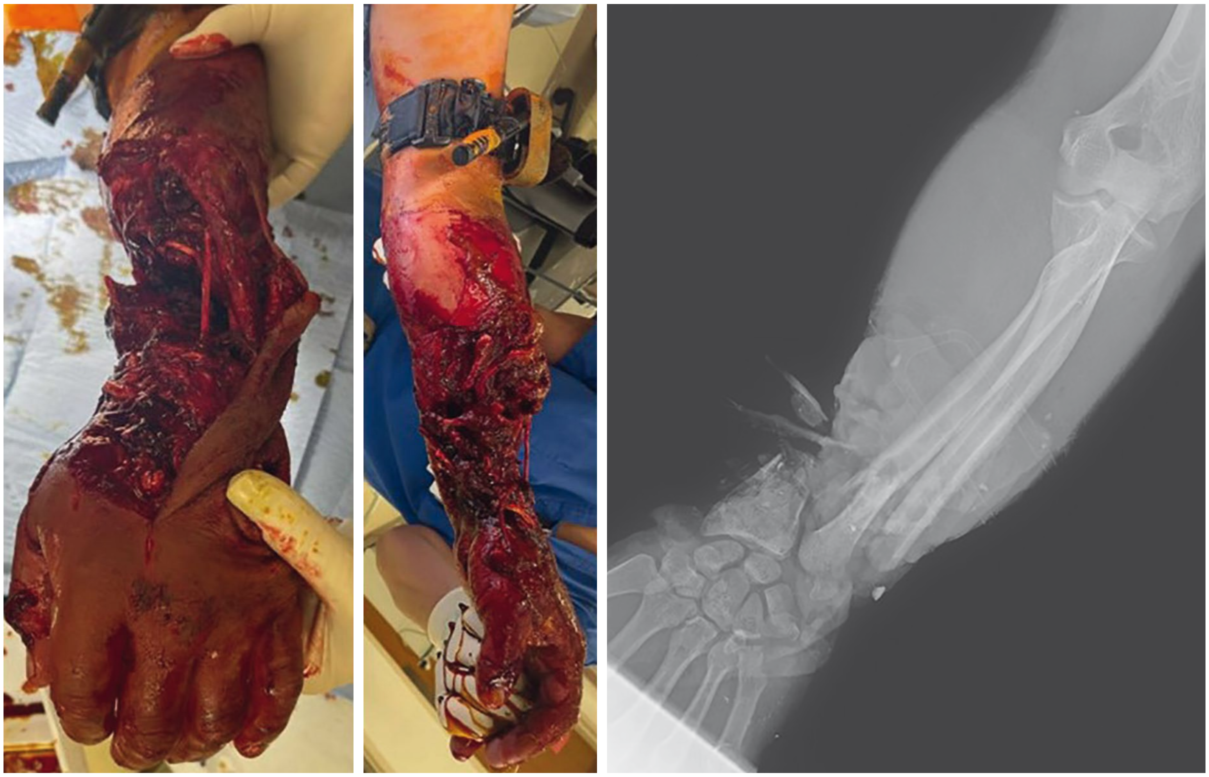

FIGURE 119.34 Left forearm crush and avulsion injury after torque mechanism when the limb was caught out the window in a rollover motor vehicle collision, with significant injury to the extrinsic flexor and extensor muscles and soft tissue degloving. X-ray of left forearm shows complete comminuted fracture of the radial shaft and greenstick fracture of the distal ulnar. The patient went on to have a transradial amputation.

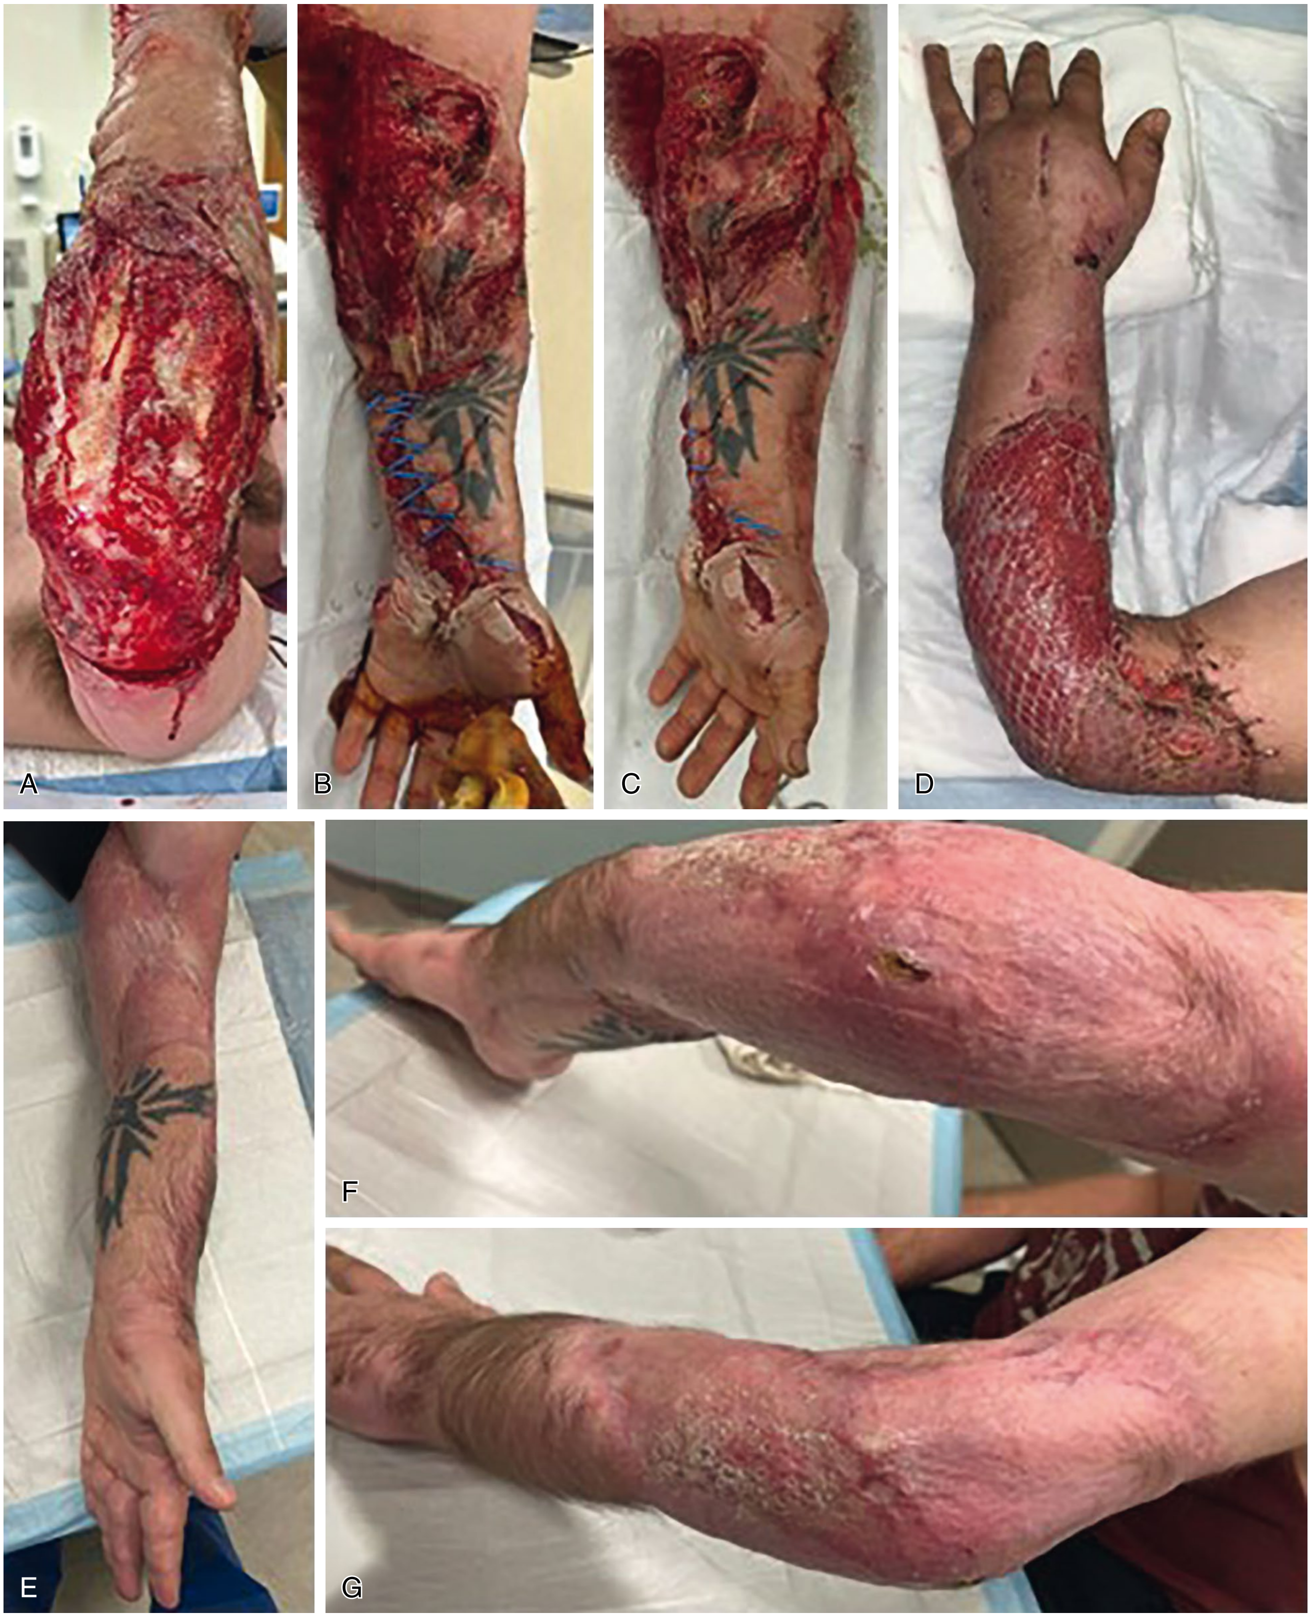

FIGURE 119.35 (A–D) Degloving injury of the proximal one-third of the forearm and crush injury resulting from being compressed between two conveyor belts for >2 hours. (E–G) Postoperative outcome after 6 months of reconstruction with skin graft. Patient sustained extensive ischemic injury to forearm flexors and high median and ulnar nerve injuries.

in description of local, pedicled flaps and microvascular free tissue transfer, reconstructive options have become more readily available for even very complex and extensive areas of soft tissue loss. Flap choice and tissue type are important considerations in these types of surgeries, especially the weight-bearing palmar surface of the hand. Tissue should be thin, pliable, and adherent to underlying structures without untoward susceptibility to shear forces, such as an adipofascial flap with skin graft or thin fasciocutaneous flap, such as the radial forearm pedicled or free flap. Consideration of vascular injuries as well as future plans for free tissue reconstruction is also important in selection, especially with ipsilateral limb pedicled flaps, such as the reverse radial forearm flap, compromising the radial artery for future use. If possible, flaps should be planned to be sensitized, at least for protective hand sensation.

Nerve and tendon repair can be conducted on a less acute basis, as described previously. Any structures identified on initial exploration requiring delayed repair should be tagged for future location. Extensor tendon injuries are often more forgiving, especially with juncturae tendinum between individual digits; however, flexor tendon injuries with multiple structures involved often have poorer prognosis for functional recovery and increased propensity for scarring and contractures. With rigid fixation, tendon gliding and early active range-of-motion protocol may still be accomplished in a controlled environment.

Mangling injuries are complex and often require creative and critical thinking. Unsalvageable structures may be used as “spare parts” for soft tissue reconstruction, such as a crushed digit soft tissue envelope being used as a fillet flap to provide glabrous tissue coverage. Although digital matching is important, in a multidigit amputation, it may be useful to replant a better-preserved digit in a heterotopic fashion, such as index or ring part onto the middle finger stump. If soft tissue and vessels are preserved, distal parts may be used as vascularized bone grafts or even free flaps, especially if a part is to be amputated proximally.[69]

INFECTIONS

Hand infections commonly present to the surgical resident covering the ED. When the infection is diagnosed and treated properly initially, most patients do well. The extent of deep palmar infections may often be underestimated during the early phases because the volar aspect of the hand does not show edema as readily as the dorsal aspect of the hand. Thus, if infections in the hand are not diagnosed at an early stage, infections may spread from one anatomic compartment to another along natural tissue planes. Hand infections can then result in significant morbidity and severe functional compromise if they are not appropriately diagnosed and treated (Fig. 119.36). Some of the more common types of infections are discussed here.

Superficial Paronychial Infections

Paronychia is the most common infection of the hand; it usually results from trauma to the eponychial or paronychial region. A paronychia may be acute (<6 weeks) or chronic (>6 weeks) in nature. The infection localizes around the nail base, advances around the nail fold, and burrows beneath the base of the nail. If pus is trapped beneath the nail, pressure on the nail evokes exquisite pain. The most common causative organism is *Staphylococcus aureus.* Traditionally, first-generation cephalosporins are recommended for empiric antibiotic treatment. However, there has now been an increasing incidence of methicillin-resistant *S. aureus* (MRSA) in community-acquired infections; therefore, in communities where MRSA prevalence is ≥10%, the provider should consider antibiotics with MRSA coverage (e.g., trimethoprim/sulfamethoxazole, clindamycin, doxycycline). After an abscess develops, surgical drainage is required. The surgical approach to an acute paronychia depends on the extent of the infection. Incisions may not be necessary. A Freer elevator is used to lift approximately 25% of the nail adjacent to the infected paronychium, extending proximally to the edge of the nail. This portion of the nail is transected, and gauze packing is inserted beneath the nail fold. A single incision to drain the affected paronychium also allows elevation of the eponychial fold when both eponychium and paronychium are involved (Fig. 119.37).[73]

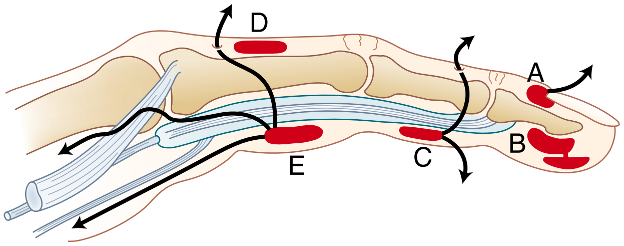

FIGURE 119.36 Spread of soft tissue infections in the hand occurs through loss of containment from the original site and erosion into and spread through contiguous anatomic compartments. (A) Paronychium. Infecting organisms access periungual tissues through fissures in the eponychial or paronychial tissues and often are discharged spontaneously in these areas. (B) Infection of pulp tissues (felon). Fibrous septa within the pulp create collar stud abscesses within the pulp. (C) Volar subcutaneous infections in the digit may be discharged percutaneously on either surface of the digit or penetrate dorsally and spread along the sheaths of the flexor or extensor tendons. (D) Subcutaneous infections on the dorsum of the digit are usually discharged percutaneously because of the thin and areolar nature of the soft tissues. (E) Proximally located digital infections or web-space infections may rupture into the palmar spaces by tracking along tendon sheaths, palmar fascia, or lumbrical canal. The continuous sheaths of the thumb and little fingers (radial and ulnar bursae) are continuous with the carpal tunnel and space of Parona at the wrist.

Infections of Intermediate-Depth Spaces

Infections of intermediate-depth spaces are pulp space infections (felons) and deep web-space infections. The pulp space infections may involve the distal, middle, or proximal volar pulp spaces and may result from direct implantation with a penetrating injury or may represent spread from a more superficial subcutaneous infection.

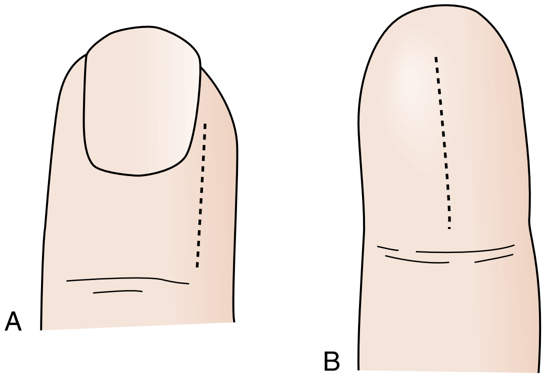

FIGURE 119.37 Incisions for paronychia (A) and felon (B).

The volar pulp of the distal digital segment is a fascial space closed proximally by a septum joining the distal flexion crease to the periosteum, where the long flexor tendon is inserted. This space is also partitioned by fibrous septa. Tension in the distal digital segment can become so great that the arteries to the bone are compressed, resulting in gangrene of the fingertip and necrosis of the distal 75% of the terminal phalanx. With infection of the digital pulp space, one must not wait for fluctuance before making the decision for surgery because of the danger of ischemic necrosis of the skin and bone. Clinical diagnosis is made by the rapid onset of throbbing pain, swelling, and exquisite tenderness of the affected pulp space. Surgical drainage is required. A single volar or unilateral longitudinal incision may be used (see Fig. 119.37). Care must be taken to design the incision to avoid the neurovascular bundles that travel on the radial and ulnar volar surface of the digit. Blunt dissection is carried down to the preperiosteal plane, and care must be taken to release any septae enclosing a fluid collection. Postoperative care includes packing of the wound and elevation of the extremity. Use of antibiotics is guided by the results of Gram staining. Similar to a paronychia, *S. aureus* is the most common causative agent. Spread from a pulp space infection may move into a joint space or underlying bone or burst through the septum proximally to involve the rest of the finger. More proximally, a pulp space infection at the base of the finger can travel through the lumbrical canal into the palm to create a deep palmar space infection.[73]

Web-space abscesses result from direct implantation or spread from a pulp space. An inflamed and tender mass in the web space separates the fingers. There is loss of the normal palmar concavity, with a widened space between the fingers. Dorsal swelling is present and must not be mistaken for the infection site. A surgical incision is placed transversely across the web space, and a longitudinal counterincision may be placed dorsally between the bases of the proximal phalanges; a generous communication is established between these two incisions (Fig. 119.38).

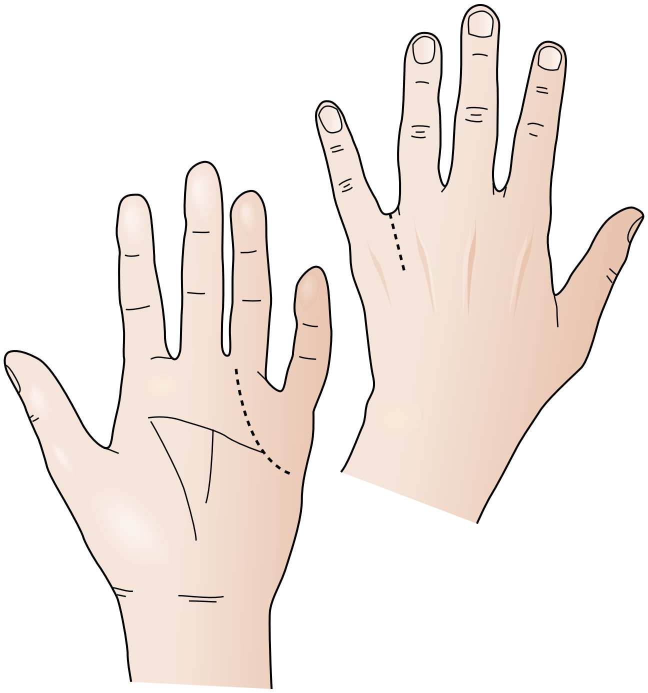

FIGURE 119.38 Incisions for web-space abscess between the little and ring fingers.

DEEP INFECTIONS

Palmar Space Infections

Palmar space infections are localized to the deep space of the hand between the metacarpals and palmar aponeurosis. A transverse septum to the metacarpal of the middle finger divides the deep space into an ulnar midpalmar and radial thenar space. The transverse head of the adductor pollicis partitions the thenar space from the retroadductor space. There may be ballooning of the palm, thenar eminence, or posterior aspect of the first web space, depending on which of the affected spaces is involved with an abscess. The dorsal subaponeurotic space of the hand deep to the extensor tendons may also be affected by an isolated infection, generally as a result of direct implantation (Fig. 119.39A). For a thenar space infection, the preferred approach to surgical drainage is a dual volar and dorsal incision (see Fig. 119.39B). On the volar side, an incision is made adjacent and parallel to the thenar crease. Great care is taken to avoid injury to the palmar cutaneous branch of the median nerve in the proximal part of the incision and the motor branch of the median nerve in a deeper plane. A second, slightly curved longitudinal incision is made on the dorsum of the first web space. Dissection is continued more deeply into this area between the first dorsal interosseous muscle and adductor pollicis. A drain is placed in the incision after thorough exploration of the respective spaces. With midpalmar space infections, dorsal swelling of the hand will be present, as is the case with all palmar infections, and must not be mistaken for the infection site. Motion of the middle and ring fingers is limited and painful. A longitudinal curvilinear incision is the preferred approach for drainage of this space (see Fig. 119.39C).[73]

Infection of Parona space occurs in the potential space deep to the flexor tendons in the distal forearm and superficial to the pronator quadratus muscle. It is usually the result of spread from the adjacent contiguous midpalmar space or from the radial or ulnar bursa. Swelling, tenderness, and fluctuation will be present in the distal volar forearm. A midpalmar infection may be associated. Active digital flexion is painful, as is passive finger extension. A surgical incision must be planned to leave the median nerve adequately covered with soft tissue.

Pyogenic Flexor Tenosynovitis

Kanavel four cardinal signs include the following: (1) the finger is held flexed because this position allows the synovial sheath its maximum volume and eases pain; (2) symmetric fusiform swelling of the entire finger is present, with edema of the back of the hand; (3) the slightest attempt at passive extension of the affected digit produces exquisite pain; and (4) the site of maximum tenderness is at the proximal cul-de-sac of the index, middle, and ring finger synovial sheaths in the distal palm or, in the case of infection of the sheaths of the thumb and little finger, more proximally in the palm. The radial and ulnar bursae communicate in approximately 80% of cases and may be simultaneously infected. Bursal infections may spread into the forearm space of Parona, deep to the flexor tendons in the distal part of the forearm, creating a horseshoe abscess.

Treatment of pyogenic flexor tenosynovitis depends on the severity of infection. Infections isolated within the finger and without systemic effects can be attempted to be managed with parental antibiotics with a plan for formal surgical washout if symptoms persist or worsen. Early infections may be drained with a limited incision and drainage over the point of maximum point tenderness or fluctuance with copious irrigation over the flexor

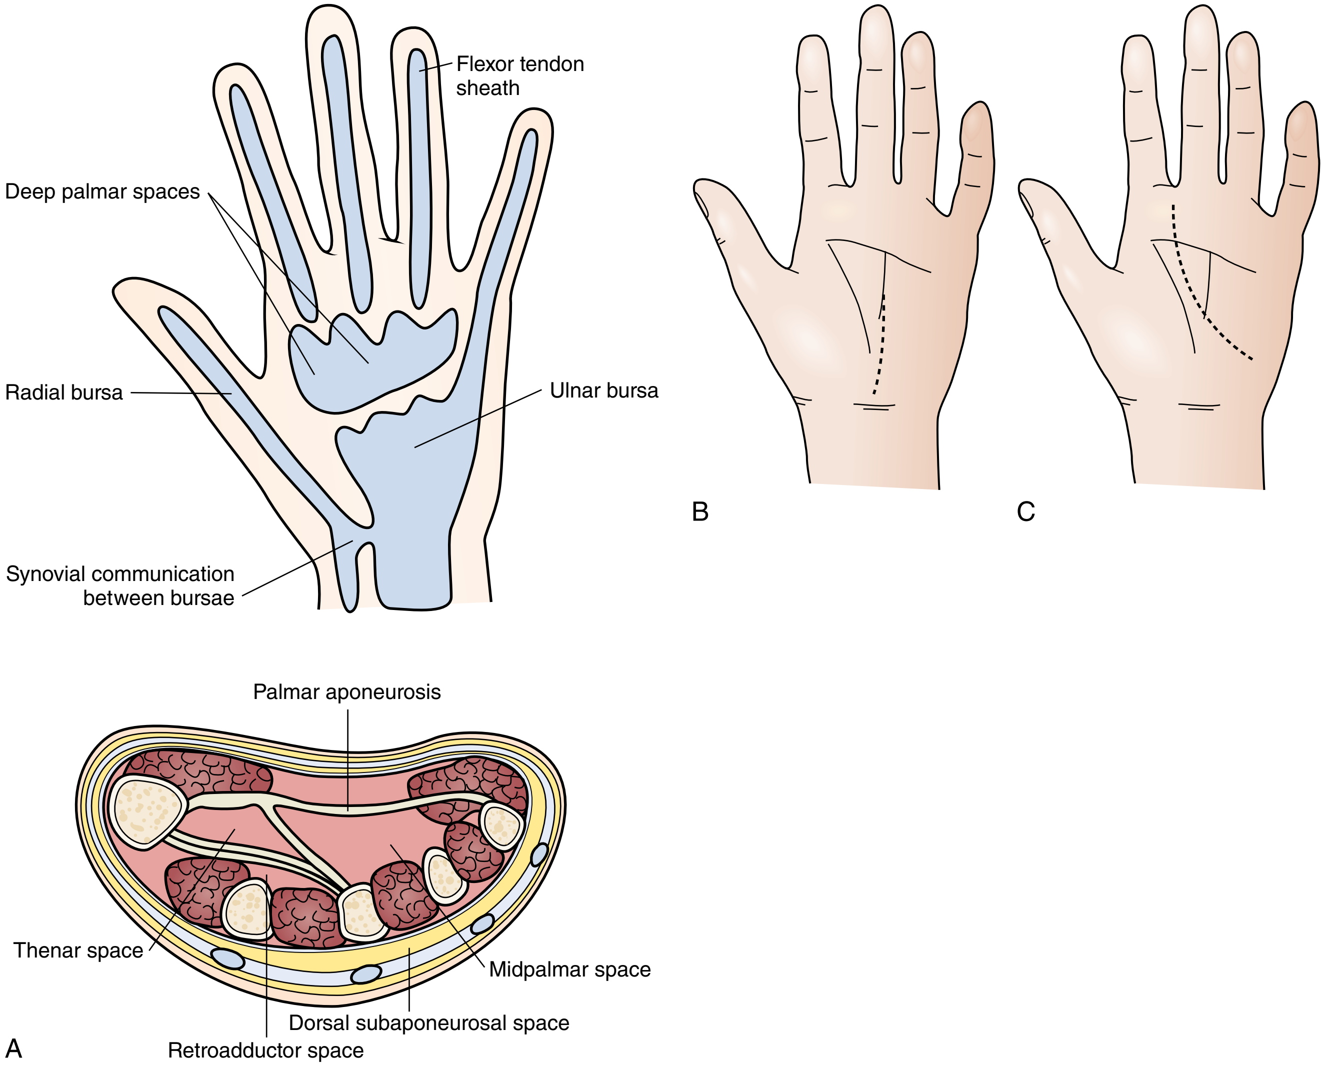

FIGURE 119.39 (A) Deep spaces of the hand and synovial bursae. Infections may be bound by these spaces or may track along anatomic dissection planes between these spaces. (B) Incision for thenar space infection. A dorsal first-web-space incision is also often required. (C) Incision for midpalmar space abscess.

sheath and tendon. When there is no purulence, this may save the patient from a more extensive surgical approach. If the infection is severe (involves multiple digits and/or systemic signs), the patient will require a semiurgent operative washout.[74]

The preferred surgical approach is through two separate incisions. The first incision is a midaxial incision made on the finger, usually on the ulnar side of the digit (on the radial side of the thumb or little finger); the digital artery and nerve remain in the volar flap, with the dissection proceeding directly to the tendon sheath. The synovium between the A3 and A4 pulleys is incised, and cloudy fluid is encountered. A second incision is made in the palm over the tendon to drain the cul-de-sac. A 16-gauge polyethylene catheter is inserted beneath the A1 pulley into the sheath, and the sheath is flushed manually with sterile saline every 2 hours after surgery. A bulky hand dressing absorbs the drainage.

Chronic and Atypical Infections

Chronic paronychia is generally the result of *Candida albicans* infection (>95%) and is not bacterial. When bacteria are involved, they are more commonly atypical mycobacteria or gram-negative organisms. Chronic paronychia generally responds to treatment with topical antifungal agents, although oral antifungal agents are sometimes used. On occasion, surgical treatment by means of marsupialization of the eponychial fold is required. If the lesion is refractory to treatment, the possibility of a malignant neoplasm is entertained.

Chronic tenosynovitis can occur in the flexor tendons or in the dorsum of the wrist and extensor tendons. It is usually of a granulomatous type and is caused by mycobacteria or fungi. Treatment includes surgical excision of the involved synovium and prolonged treatment with the appropriate antimicrobial agents. Chronic infected tenosynovitis must be differentiated from other causes of chronic granulomatous synovitis, such as sarcoidosis, amyloidosis, gout, and rheumatoid arthritis.

Herpetic Whitlow

Herpetic whitlow is caused by type 1 or type 2 herpes simplex virus and may be confused with a paronychia. Infection begins with the appearance of small clear vesicles with localized swelling, erythema, and intense pain. The vesicles may subsequently appear turbid and coalesce over the next few days before ulcerating. Diagnosis is confirmed by culturing the virus from the vesicular fluid, assessing immunofluorescent serum antibody titers, or performing a Tzanck smear. However, these measures are rarely required because clinical diagnosis is usually sufficient. Infection can occur from autoinoculation from an oral or genital lesion or exposure as a healthcare worker. Pain is often out of proportion to the physical findings. Treatment is generally nonoperative because this infection is usually self-limited. Antivirals such as acyclovir or famciclovir may be of some benefit if started within the first 48 hours of symptom onset. Surgical incision and drainage can lead to systemic involvement and possible viral encephalitis.

Animal and Human Bites

The most striking difference in the microbial flora of human and animal bite wounds is the higher number of bacterial isolates per wound in human bites, the difference being mostly caused by the presence of anaerobic bacteria. Human bites can occasionally transmit other infectious diseases, such as hepatitis B, tuberculosis, syphilis, or actinomycosis. The incidence of *Eikenella corrodens* in human bite infections of the hand has been reported to vary between 7% and 29%. Usually, isolated organisms from infected human bite wounds are, as in animal bites, α-hemolytic streptococci and *S. aureus,* β-lactamase–producing strains of *S. aureus,* and *Bacteroides* spp. Anaerobic bacteria, including *Bacteroides, Clostridium, Peptococcus,* and *Veillonella,* are more prevalent in human bite infections than previously recognized. Most studies of animal bite wounds have focused on the isolation of *Pasteurella multocida,* disregarding the role of anaerobes. However, more recent studies have shown that dog bite wounds indicate multiple organisms, with *P. multocida* being isolated from only 26% of dog bite wounds in adults. Most animal bites cause mixed infections of aerobic and anaerobic bacteria.

Pyogenic joint infections usually result from trauma, such as a bite wound from a tooth when the assailant's hand strikes the jaw. A tooth struck by the clenched fist of an attacker penetrates the skin, tendon, joint capsule, and metacarpal head. Once the finger is extended, the four puncture wounds separate from each other to create a closed space within the joint. All these so-called fight bite wounds of the MPJ need to be explored surgically, debrided, and thoroughly lavaged. Human bite wounds are not closed primarily and are treated with appropriate antibiotics.

COMPARTMENT SYNDROME, HIGH-PRESSURE INJECTION INJURIES, AND EXTRAVASATION INJURIES

Compartment Syndrome

Compartment syndrome results in symptoms and signs caused by increased pressure within a limited space that compromises the circulation and function of the tissues in that space. Volkmann ischemic contracture is the sequala of untreated compartment syndrome; it results in muscle that is fibrosed, contracted, and functionless and nerves that are insensible. Various injuries are known to cause compartment syndrome:

- Decreased compartment volume (e.g., from externally applied tight dressings or casts, lying on a limb in a comatose state)
- Increased compartment content (e.g., from bleeding or trauma with fractures or finger injuries; increased capillary permeability, such as reperfusion after ischemic injury; electrical burn injuries)
- Other injuries (e.g., snakebites, high-pressure injection injuries)[75]

The diagnosis of compartment syndrome is based primarily on clinical evaluation. Although it is possible to measure compartment pressure, the decision to perform fasciotomy is based on a high degree of clinical suspicion. Compartment ischemia may be severe and still not affect the color or temperature of the distal fingers, and the distal pulses are rarely obliterated by compartment swelling. However, circulation in the muscle and nerve may be greatly reduced. Muscle ischemia that lasts for more than 4 hours leads to muscle death and may also cause significant myoglobinuria. After 8 hours of total ischemia, irreversible nerve changes are complete. The hallmark of muscle and nerve ischemia is pain, which is progressive and persistent. The pain is accentuated by passive muscle stretching; this is the most reliable clinical test for diagnosis of compartment syndrome. The next most important clinical finding is diminished sensation, which indicates nerve ischemia. The closed compartments of the forearm and hand are also palpated and found to be tense and tender, confirming the diagnosis of compartment syndrome. A passive muscle stretch test elicits severe pain in the presence of compartment syndrome. An arterial injury and nerve injury need to be distinguished in the differential diagnosis of compartment syndrome. All three of these injuries produce paresthesias and paresis; pain with passive stretch is present in compartment syndrome and arterial occlusion but not in neurapraxia; and pulses are intact in compartment syndrome and neurapraxia but not with arterial occlusion. In situations in which the patient cannot cooperate because of inebriation or unconsciousness and the clinical diagnosis is difficult, compartment pressure can be measured.[75]

Release of a forearm compartment syndrome always requires carpal tunnel release (Fig. 119.40). The palmar incision starts in the valley between the thenar and hypothenar muscles, and the incision then curves transversely across the flexion crease of the wrist at the ulnar border. This incision must avoid the palmar cutaneous branch of the median nerve and prevent flexion contracture across the wrist crease. It also provides an opportunity to release the Guyon canal. The incision then extends proximally up the forearm before curving back in a radial direction so as to have a large skin flap that will cover the median nerve and distal forearm tendons. At the elbow, the incision for the flap then curves again across the antecubital fossa, providing cover for the brachial artery and median nerve and preventing linear contracture across the antecubital fossa. The dorsal and so-called mobile wad compartments of the forearm are readily released through a straight incision, as needed. Appropriate release of the various intrinsic compartments of the hand may also be required. Most wounds can be partially closed at 5 days. If the skin cannot be closed secondarily within 10 days, a split-thickness skin graft can be applied.

High-Pressure Injection Injuries

High-pressure injection injuries to the hand are relatively uncommon, but consequences of a misdiagnosis are serious. Urgent treatment is required. High-pressure injection guns are used for painting, lubricating, cleaning, and farm animal vaccinations. Materials that may be injected with these devices include paint, paint thinners, oil, grease, water, plastic, vaccines, and cement. These high-pressure injection guns may generate pressures ranging between 3000 and 12,000 psi. Injection injuries can also be caused by other sources, such as defective lines and valves, pneumatic hoses, and hydraulic lines. The type of material injected is the most important prognostic factor. Oil-based paints and paint thinners can generate significant early inflammation, leading to severe fibrosis. Because tendon sheaths at the index, middle, and ring fingers

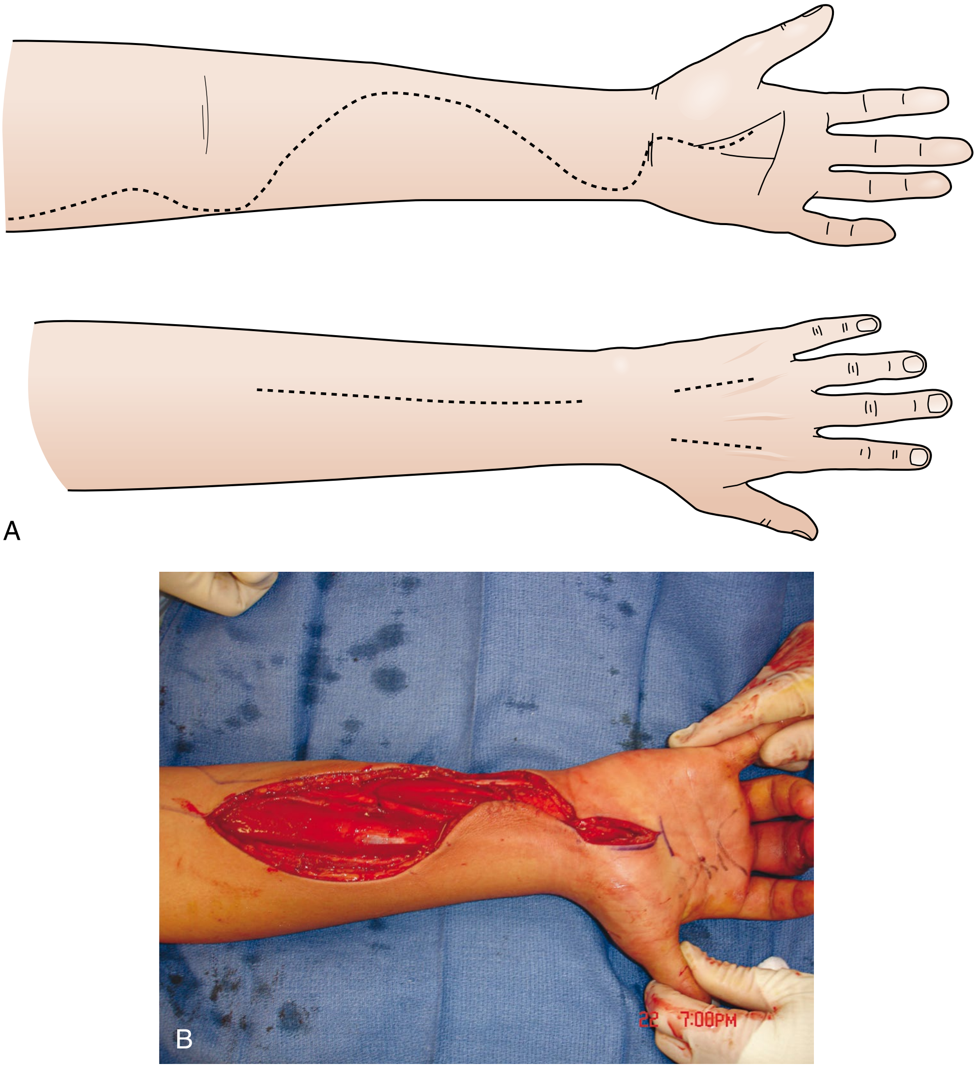

FIGURE 119.40 (A) Incisions for forearm fasciotomy. (B) Fasciotomy in a child for compartment syndrome after a snakebite.

end at the level of the MPJs, material injected at the distal interphalangeal (DIP) or proximal interphalangeal (PIP) flexion creases will remain within these digits. However, tendon sheaths at the thumb and little finger extend all the way into the radial and ulnar bursae. Thus, material injected at the little finger or at the IP flexion crease of the thumb may potentially extend all the way into the forearm and may even cause a compartment syndrome.[76]

Initial presentation of a patient with a high-pressure injection may be benign and subtle. This may result in mismanagement by minimizing the patient's complaints. The break in the skin may be a benign-looking, pinhole-sized puncture site. However, within several hours, the digit becomes increasingly more painful, swollen, and pale. Prompt recognition and realization of the severity of injury are paramount. Radiographs may help determine the extent and dispersion of the injected material, either in the form of subcutaneous emphysema or, with lead-based paints, appearing as radiopaque soft tissue densities. The entire digit must be surgically decompressed, and all foreign material and necrotic tissue must be debrided. Wounds are closed loosely over Penrose drains or in a delayed manner. Appropriate antibiotics must be administered. Despite prompt recognition and treatment, many such injuries ultimately result in surgical amputation of the digits.[76]

Extravasation Injuries

In the past, extravasation injuries from chemotherapeutic agents frequently affected the upper extremity. However, subcutaneously tunneled central lines have now reduced the incidence of these injuries. If extravasation is suspected, infusion must be stopped immediately. Cold packs are applied for 15 minutes four times a day, and the extremity is elevated during the next 48 hours. This treatment is generally effective for most extravasation injuries. It is critical to determine the agent that has infiltrated because specific antidotes have been described. Hyaluronidase injected along the periphery infiltrated tissue is a potential treatment of choice, helping to dissipate the agent along tissue planes. However, if blistering, ulceration, and pain occur in the damaged tissue, progressive necrosis to the limits of the extravasation will follow, and surgical excision of all damaged tissue is necessary. Most subsequent wounds can generally be treated with delayed split-thickness skin grafting, although the options for wound coverage after debridement depend on the extent of the debridement that was required.[77]

TENOSYNOVITIS

De Quervain Disease

De Quervain disease is a stenosing tenosynovitis of the first dorsal compartment of the wrist and is a common cause of pain and disability. Diagnosis is easily made from a history of pain localized to the radial side of the wrist and aggravated by movement of the thumb. There is frequently a history of chronic overuse of the wrist and hand. Other features are local tenderness and swelling over the first dorsal compartment of the wrist and a positive Finkelstein test result—the patient clasps the thumb, and brisk ulnar deviation to the hand elicits extreme pain. Crepitus may be palpable. This condition must be differentiated by radiographic and physical examination from arthritis of the thumb carpometacarpal joint.[78]

Nonoperative treatment includes local steroid injection, thumb and wrist immobilization, local heat, and systemic antiinflammatory medications. If these nonoperative measures fail, surgical decompression of the first dorsal compartment at the wrist is performed. Care must be taken to protect the radial sensory nerve branches during the course of the operation because these branches traverse just under the skin in this area, and trauma or transection may lead to painful, disabling neuromas.[78]

Intersection Syndrome

Intersection syndrome is not well understood but is characterized by pain and crepitus at the point at which the APL and EPB tendons cross over the tendons of the second dorsal compartment (ECRL and ECRB; Fig. 119.41). Initial treatment is by splinting, local corticosteroid injection, and antiinflammatory medications. Refractory cases require surgical release at the second dorsal compartment and excision of involved tenosynovial membranes.

Trigger Thumb and Fingers

Trigger finger is a constricting tenosynovitis of the flexor tendons, generally at the level of the A1 pulley. The patient can flex the digit, but an apparent nodule catches at the proximal edge of the A1 pulley, locking the PIPJ (or the IPJ of the thumb) in this flexed position. Attempts at extending the digit cause it to snap back suddenly, much like the trigger of a gun. Often, the patient needs to use the opposite hand to unlock and extend the digit. In its most severe form, the constriction is so tight that the patient cannot flex the digit, or it becomes fixed in a flexed position and can no longer be fully extended. A congenital form of trigger thumb or finger presents in infants, but most cases resolve by the time the child reaches 1 year of age; if not, an operation is indicated. Nonoperative treatment in adults includes local injection of corticosteroids. If this regimen fails, the A1 pulley is longitudinally divided by surgery.[78,79]

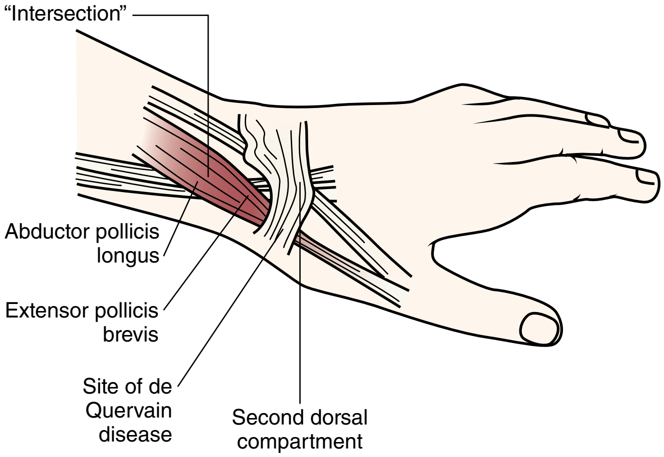

FIGURE 119.41 Anatomic locations for de Quervain stenosing tenosynovitis and intersection syndrome.

Other Sites of Tenosynovitis

Other sites include the FCR and FCU tendons. They can frequently be treated by splinting and local corticosteroid injection, although surgery occasionally may be required. Inflammation of the ECU may also be an enigmatic cause of ulnar-sided wrist pain. Diagnosis is made by eliciting tenderness along the ECU tendon, pain on active resisted extension, and ulnar deviation of the wrist.

NERVE COMPRESSION SYNDROMES

Along the length of the upper extremity, nerves pass through a number of anatomic bottlenecks. These are all possible sites of nerve entrapment and lead to characteristic distal sensory and motor deficits. The most common sites of nerve compression, from proximal to distal along the length of the extremity, are at the nerve root secondary to cervical disc disease or cervical degenerative arthritis, thoracic outlet compression at the level of the clavicle, ulnar nerve entrapment at the elbow (cubital tunnel syndrome), entrapment of the PIN in the proximal forearm (radial tunnel syndrome, posterior interosseous syndrome), entrapment of the median nerve and its branches in the proximal forearm (so-called pronator syndrome, anterior interosseous nerve syndrome), and, finally, entrapment of the median nerve at the wrist (carpal tunnel syndrome) and of the ulnar nerve in the Guyon canal (ulnar tunnel syndrome).

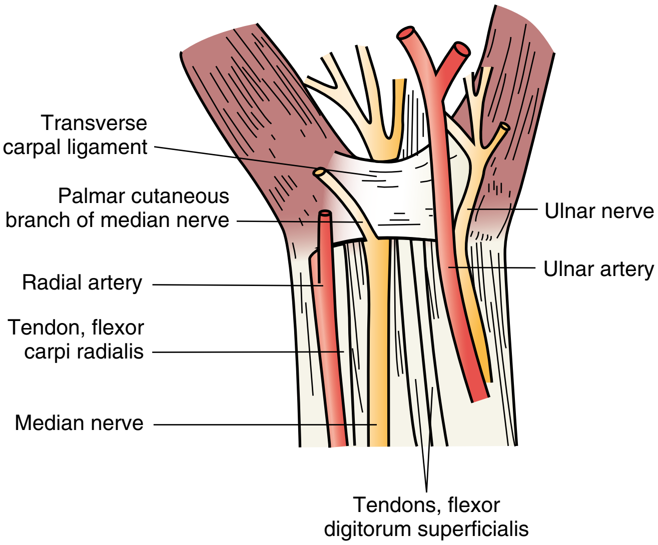
In most cases of nerve entrapment, no specific aggravating causative factor is found. An increasing incidence of compression neuropathy is reported in patients whose work involves chronic repetitive stress. In some, there may be a clearly defined extrinsic compressive problem on the nerve or an aggravating factor. These include the following:

- Trauma that can produce bone compression, for example, carpal tunnel after carpal dislocations or a distal radius malunion (median) and supracondylar humerus fractures that increase the elbow carrying angle (ulnar nerve at the elbow)
- Synovial thickening of the bursa in rheumatoid arthritis in the carpal tunnel (median) or at the elbow (posterior interosseous)
- Tumors such as giant cell tumor in the Guyon canal (ulnar) or a lipoma in the radial tunnel (posterior interosseous)
- Developmental, with anomalous muscles present in the carpal tunnel (median), Guyon canal (ulnar), or forearm (median)
- Metabolic, in which disturbances of fluid balance cause increased pressure on the nerve, particularly at the carpal tunnel (e.g., myxedema, pregnancy)

Carpal tunnel syndrome is the most common peripheral nerve entrapment syndrome, followed by ulnar nerve entrapment at the elbow.[80] The other entrapment syndromes are less common. Diabetes mellitus is recognized as a risk factor for carpal tunnel syndrome, and the response to treatment has previously been unclear. However, studies suggest that patients with diabetes do similarly well as patients who are normoglycemic do after carpal tunnel release.

Carpal Tunnel Syndrome

The carpal tunnel is a packed fibro-osseous tunnel at the wrist that is traversed by the median nerve and nine long extrinsic digital



Transverse carpal ligament
Palmar cutaneous branch of median nerve
Radial artery
Tendon, flexor carpi radialis
Median nerve
Ulnar nerve
Ulnar artery
Tendons, flexor digitorum superficialis

FIGURE 119.42 Anatomy of the carpal tunnel. The transverse carpal ligament (flexor retinaculum) is divided longitudinally during a carpal tunnel release. *DIP*, Distal interphalangeal joint.

flexor tendons (Fig. 119.42). Its floor is formed by the carpal bones and roofed by the flexor retinaculum (transverse carpal ligament). Normal pressures in this tunnel are 20 to 30 mm Hg. A rise in pressure above this causes a chronic compressive ischemic injury to the nerve segment, resulting first in demyelination and eventually in axonal death. There is progressive conduction block in the nerve, with subsequent sensory and motor dysfunction. The earliest symptoms are pain and paresthesias, which are characteristically more obvious at night, after prolonged activity, and with positional postural changes at the wrist, such as when driving, using a handheld hair dryer, or reading a book. The patient may complain of clumsiness and a tendency to drop objects. The paresthesias characteristically follow the distribution of the median nerve, including the thumb and the index and middle fingers.

Physical examination consists of compressing the carpal canal, percussing the median nerve, and hyperflexing the wrist to produce paresthesias (Durkan sign, Tinel sign, and Phalen test, respectively). Sensory evaluation reveals hypoesthesia in the distribution of the median nerve and may reveal a widened two-point sensory discrimination. Thenar weakness or muscle wasting is a late finding. Nerve conduction studies and electromyography are useful adjuncts to the clinical examination.

Initial treatment of carpal tunnel syndrome includes use of wrist splints (especially at night), occasional local corticosteroid injections, and modification of work patterns. If symptoms persist or if the initial presentation shows severe carpal tunnel syndrome, surgical decompression is required. This is performed by longitudinally dividing the flexor retinaculum by open or endoscopic means. Both the Agee (single-portal) and Chow (two-portal) procedures have shown similar efficacy to the open approach.[81] Synovectomy and removal of any mass lesion may also be required if that is the cause of the problem.[82]

Pronator Syndrome

In the proximal forearm, the median nerve may be compressed at the fibrous arch between the two heads of the FDS, two heads of the pronator teres, lacertus fibrosus (bicipital aponeurosis at the elbow), and ligament of Struthers. Compression at any or all of these sites is loosely grouped under the pronator syndrome. The symptoms produced are similar to those of carpal tunnel, although nocturnal symptoms are uncommon. The palm may also feel numb because the palmar cutaneous branch is involved, but it is specifically spared in carpal tunnel syndrome because that nerve branch passes superficial to the flexor retinaculum and arises proximal to the retinaculum. Symptoms may be reproduced or worsened by attempting pronation against resistance and by resisted flexion of the middle finger. However, it may be difficult to locate the compressive cause in the pronator syndrome precisely, and surgical decompression often involves release of all four potential sites of compression.

The anterior interosseous nerve branch of the median nerve may occasionally be compressed in isolation. This does not produce any sensory symptoms but specifically targets the three muscles innervated by the anterior interosseous nerve—FPL, FDP to the index and middle fingers, and pronator quadratus.

Ulnar Nerve Compression

The ulnar nerve may be compressed in the Guyon canal at the wrist or in the so-called cubital tunnel at the elbow and distal upper arm.

Guyon Canal Compression

The Guyon canal is bounded by the hook of the hamate, pisiform, pisohamate ligament, and palmar carpal ligament. Compression by mass lesions, including a ganglion, giant cell tumor, ulnar artery thrombosis, and ulnar artery aneurysm, may occur at this site as in hypothenar hammer syndrome. Compression at this site may also be idiopathic. Distal ulnar deficits may be in the motor or sensory distribution or both, depending on where in the canal the compression occurs relative to the takeoff of the deep motor branch of the ulnar nerve. Tinel sign may be present, and there may be worsening of symptoms by direct compression over the Guyon canal. Treatment is surgical; it consists of dividing the palmaris brevis muscle and palmar carpal ligament as well as removing any offending mass in this region.

Cubital Tunnel Syndrome

The cubital tunnel is a long tunnel starting in the distal upper arm and extending into the proximal forearm. As the ulnar nerve passes into the forearm, it curves tightly around the grooved posterior and inferior surfaces of the medial epicondyle of the humerus. This groove is bridged by the aponeurosis between the two heads of the FCU, the leading edge of which may be thickened and fibrosed, called *Osborne ligament.* More proximally, the ulnar nerve passes from the anterior compartment of the arm into the posterior compartment, which may be bridged by a long tunnel called the *arcade of Struthers.* The medial intermuscular septum in the upper arm may also cause ulnar nerve compression. The most distal fibro-osseous tunnel is more accurately termed the *cubital tunnel.* However, compression on the ulnar nerve can occur at any of these sites, proximal to distal, starting in the upper arm and extending into the forearm. Motor and sensory symptoms develop in the distribution of the ulnar nerve and are worsened by adopting a flexed position at the elbow. Examination reveals Tinel sign over the tunnel. Paresthesias are described in the distribution of the ulnar nerve to the little and ring fingers and ulnar border of the hand. A differential diagnosis includes thoracic outlet syndrome, compression of the ulnar nerve in the Guyon canal, and nerve root compression in the neck.

Initial treatment consists of splinting the elbow in extension at night. Use of soft extension elbow pads prevents elbow flexion and direct pressure on the nerve. Failure of nonoperative measures and significant changes in electrodiagnostic studies are indications for surgical decompression. Usually, all the fibrous restraints on the ulnar nerve around the elbow are released, and the nerve is transposed anteriorly to the medial epicondyle into a subcutaneous or submuscular position. There have been preliminary reports of success with endoscopic in situ decompression of the ulnar nerve at the elbow.

Radial Nerve Compression

The radial nerve may be compressed proximally in the triangular space in the axilla (specifically involving the axillary branch), spiral groove posterior to the humerus in the arm, and lateral intermuscular septum proximal to the elbow. More distally in the forearm, the PIN, the principal motor division of the radial nerve, can be compressed in the so-called radial tunnel, starting at the leading fibrous edge of the supinator (ligament of Frohse). There may be a variable degree of interosseous nerve paresis, or there may be pain radiating down the dorsoradial aspect of the forearm (called *radial tunnel syndrome*). Initial treatment is nonoperative with splinting, but if this fails, surgical decompression may occasionally be required.[83]

Thoracic Outlet Compression

The thoracic outlet is a narrow space at the base of the neck bounded by the first rib medially, scalenus anterior muscle and clavicle anteriorly, and scalenus medius muscle posteriorly. All elements of the brachial plexus as well as the subclavian artery and vein pass through this narrow space and can be potentially compressed at this site. A Tinel sign can often be elicited at the supraclavicular and infraclavicular regions. A Roos test is performed by asking the patient to hold both arms overhead in a surrender position while opening and closing the fists. This reproduces symptoms within 1 minute, and if continued, the arm collapses at the side. Adson test involves palpating the radial pulse while the patient turns the chin toward the same side, inhales deeply, and holds their breath. The radial pulse disappears or diminishes. The costoclavicular compression test involves sustained downward pressure on the clavicle, and the symptoms are reproduced. Radiographic evaluation may reveal a cervical rib. Results of nerve conduction studies are often normal.

Thoracic outlet compression may occur in association with other peripheral sites of nerve compression, a condition termed *double-crush syndrome.* Treatment is primarily nonoperative, involving posture-improving exercises and avoidance of aggravating activities. If symptoms persist, especially if they are associated with vascular compression, the thoracic outlet may be surgically decompressed. This is accomplished by a transcervical or transaxillary resection of the first rib, often with release of the scalene muscles.

TUMORS

Ganglions and mucous cysts represent 60% to 70% of hand tumors, followed in frequency by inclusion cysts, warts (verrucae), giant cell tumors in tendon sheaths, foreign body granulomas, lipomas, hemangiomas, and pyogenic granulomas (Table 119.9). Benign tumors account for 95% of hand neoplasms. Squamous cell carcinoma is the most frequent primary malignant neoplasm of the hand, basal cell carcinoma is rare, and melanoma is relatively uncommon in the upper extremity. Acral lentiginous melanoma (e.g., in the palm, sole, or nail bed) has a tendency for early metastasis. Primary bone tumors of the hand are generally benign; the most common are enchondromas and osteochondromas. Giant cell tumors of bone in the hand are rare, occurring usually in the distal radius. They are locally aggressive and may occasionally metastasize. Of malignant bone tumors, only 1.2% affect the hand. Although bone metastases in other parts of the body are relatively common, bones of the hand are rarely affected by metastases from other sites.[84,85]

Soft tissue sarcomas are rare, representing 1% of all malignant neoplasms of the body, excluding skin tumors. Although uncommon, certain types predominate in the hand. Epithelioid, synovial, and clear cell sarcomas are relatively rare in other sites but, by comparison, are more common in the hand.

Within the spectrum of benign and malignant tumors, there is a group with intermediate malignancy. Giant cell and desmoid tumors (of soft tissue) have a propensity for local recurrence after surgical excision. Their histologic patterns may belie their behavior. Juvenile aponeurotic fibroma and nodular fasciitis may appear histologically more aggressive than desmoid tumors but are self-limited. The tiny glomus tumor is uncommon but has a propensity for the fingertips and subungual regions. It may be an enigmatic cause of severe and exquisite pain at the fingertips and can be recognized by a pinpoint site of extreme local tenderness and a violaceous hue deep to the nail plate. MRI may occasionally detect these tiny lesions at the fingertip.

If a lesion is thought to be benign, excision without further workup, except perhaps for routine radiographs, is appropriate. However, if a primary malignant neoplasm of bone or soft tissue is suspected, additional studies must be undertaken before biopsy. CT may help delineate tumor boundaries. Desmoid tumors have radiographic density identical to that of muscle and are better demonstrated by MRI.

Soft Tissue Tumors

Ganglion Cysts

Ganglions are formed by an outpouching of the synovial membrane from a joint or tendon sheath. They contain thick, jellylike, mucinous material similar in composition to synovial fluid (Fig. 119.43). Of ganglions, 60% occur on the dorsal aspect of the wrist, arising in the region of the scapholunate ligament. Other sites for ganglions in the hand are at the volar wrist, arising from one of the scaphoid articulations; at the flexor tendon sheath at the area of the A1 pulley; and at the dorsum of the DIPJ, called a *mucous cyst,* where they are often associated with osteoarthritis of that DIPJ. In the last location, the ganglion cyst can exert pressure on the germinal matrix of the nail bed, resulting in a deformed or grooved nail.

Ganglions are most common in females in the third decade of life. They are innocuous and can often be left alone. However, treatment may be required for cosmetic purposes or to relieve pressure effects on adjacent structures (Fig. 119.44). The dorsal wrist ganglion can sometimes be painful as a result of pressure on the PIN at that location. A very small impalpable dorsal wrist ganglion can become quite painful, the so-called occult ganglion, and on occasion may best be diagnosed by MRI. Treatment of a dorsal wrist ganglion may be performed by aspiration of the mucinous substance with a large-bore needle. If this fails, the ganglion can then be surgically excised. Care must be taken to trace and resect the pedicle of the ganglion all the way down to the joint or tendon sheath from which it arises. A volar wrist ganglion may often be closely related to the radial artery. Aspiration of

TABLE 119.9 Benign Connective Tissue Tumors of the Hand

SOFT TISSUE TUMORS	PRESENTATION	MOST COMMON LOCATIONS	TISSUE OF ORIGIN AND APPEARANCE	TREATMENT	RADIOGRAPHIC APPEARANCE
Ganglion	Swelling, sometimes painful; DIP mucous cyst may spontaneously drain clear gelatinous fluid; 70% of hand swellings	Volar and dorsal wrist, flexor tendon sheath, dorsum of DIP joint	Synovial cyst containing thick gelatinous fluid	No treatment versus aspiration versus excision	No radiographic alterations; mucous cyst at DIP joint may have osteophytes associated with osteoarthritis
Giant cell tumor of tendon sheath	Progressive enlargement, painless, deeply adherent; potential recurrence after excision; second most common hand tumor	Any synovial site, including tendon sheath, joint, palmar plate, usually in a digit	Synovium and histiocytes; bosselated and yellow-brown color from hemosiderin pigmentation	Excision	Pressure resorption of bone
Lipoma	Painless enlarging mass, usually on volar surface of hand or finger; may reach very large size; seldom nerve compression symptoms	Volar hand and finger	Mature fat cells	Excision (shell out)	Characteristic water-clear appearance on radiograph
Inclusion cyst (implantation dermoid)	Painless, enlarging lesion, adherent to overlying dermis; more common in laborers and those subject to minor hand trauma; may become infected	Palm and fingertips	Implanted epidermis cyst containing keratinous debris	Excision of entire epithelium-lined sac	May cause pressure resorption of bone
Neurofibroma	May be localized, diffuse, or plexiform; may be associated with von Recklinghausen disease; painless enlargement, but pain arouses suspicion of malignant change	Less common on hand than elsewhere; seen more frequently on palm	Perineurial fibroblasts	Excision if noncritical nerve; biopsy if malignancy suspected; possible nerve grafting	Characteristic MRI lobulated appearance
Schwannoma	Painless small mass in a peripheral nerve that is laterally mobile; may be an incidental finding at time of carpal tunnel surgery; occasional distal dysesthesias	Median and digital nerves	Schwann cells	Microneural surgery can shell the tumor out of the nerve without leaving neurologic deficit	No changes on plain radiograph
Pyogenic granuloma	Often at site of previous trivial skin injury on the fingers; friable and bleeds easily; grows rapidly	Fingers	Granulation tissue	Small lesions can be cauterized; excise larger lesions	No radiographic changes
Glomus tumor	Very small lesions; exquisitely painful, localized tenderness, cold sensitive; patients sometimes labeled as malingering	Subungual or volar fingertip; may be multiple	Neuromyoarterial apparatus	Excision; repair nail bed if subungual	May show indentation of distal phalanx

DIP, Distal interphalangeal.

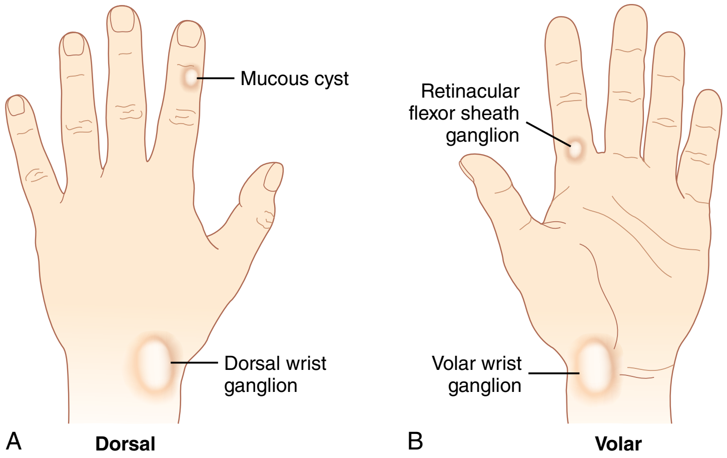


FIGURE 119.43 Dorsal (A) and volar (B) aspects of the hand and wrist showing common types of ganglions, including the dorsal wrist ganglion, volar wrist ganglion, flexor sheath ganglion (volar retinacular cyst), and mucous cyst.

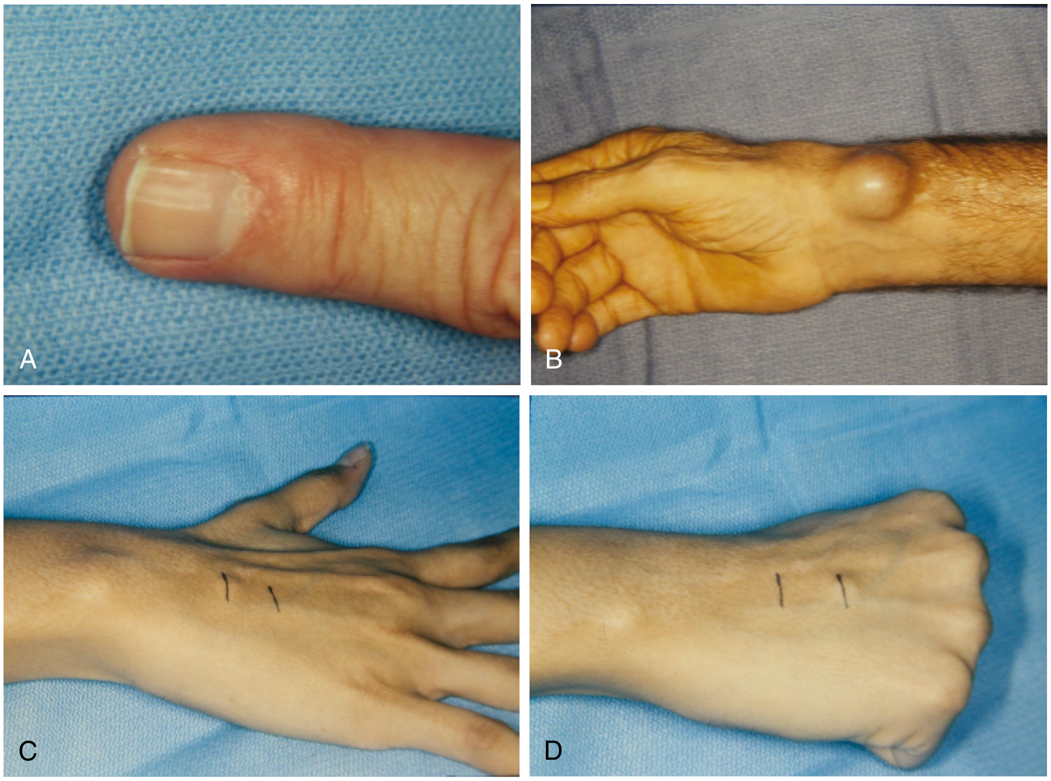

FIGURE 119.44 Ganglions in the hand. (A) Ganglion associated with osteoarthritis of the distal interphalangeal joint (mucous cyst), causing longitudinal linear groove in the nail plate from pressure on the germinal matrix. (B) Volar wrist ganglion on the radial side of the flexor carpi radialis tendon is closely related to the radial artery and should not be aspirated. (C) Ganglion arising from the extensor digitorum communis tendon of the ring finger located at the level of the proximal skin marking with fingers extended. (D) Movement of ganglion 2 cm to the level of the more distal skin marking when the fist is clenched. Distal movement of the swelling with the gliding extensor tendon confirms its attachment to the tendon.

volar wrist ganglions is seldom advised because of the potential risk of injury to the radial artery. At the level of the DIPJ, optimal treatment includes not only meticulous excision of the ganglion but also the removal of associated osteophytes from the joint. Arthroscopic decompression of dorsal wrist ganglions has been described.

Giant Cell Tumor

Giant cell tumor, also called *pigmented villonodular synovitis,* is the second most common hand tumor. It occurs in soft tissues (e.g., synovial membrane of joints, tendon sheaths) and, less commonly, in bone. This yellow-brown multilobular tumor is composed of multinucleated giant cells. Although usually benign, the tumor pushes deeply into the soft tissues of the digits and extends along tendon sheaths and around neurovascular structures. It is frequently asymptomatic and is often larger than suspected clinically. Radiologic notching of bone may be evident in larger, soft tissue giant cell tumors. Complete surgical excision is the treatment of choice. Failure to discern and remove each lobule substantially increases the reported local recurrence rate of almost 10%. Synovectomy of the joint of origin may be necessary (Fig. 119.45).

Epidermal Inclusion Cysts

Epidermal inclusion cysts, also called *implantation dermoids,* frequently occur after trauma as keratin-producing epidermal cells become lodged in the subcutaneous tissues (see Fig. 119.45). The resulting cystic mass contains a thick toothpaste-like material. They occur more commonly in males, especially in manual laborers, and most frequently involve the palm of the hand and fingertips. They may also occur in previous surgical scars. Treatment is surgical excision, and recurrence is rare.

Lipoma

Lipomas are small, benign, soft, fluctuant, fatty tumors (Fig. 119.46). In the hand, they usually occur on the thenar eminence. Although generally painless, they may enlarge significantly, insinuating into deep palmar spaces and causing pain by compression on adjacent nerves. Intracarpal lipoma is a rarer cause of carpal tunnel syndrome. Resection of symptomatic lipomas is curative, although 1% to 2% may recur.

Pyogenic Granuloma

Pyogenic granuloma is a misnomer for an exuberant outburst of highly vascular granulation tissue at the site of previous relatively trivial trauma. These lesions are friable, bleed easily, and may grow rapidly. They respond to curettage or simple excision. They usually occur on the fingertips. Histologic confirmation of the diagnosis is necessary because of occasional confusion with aggressive malignant lesions, such as ulcerated, amelanotic, malignant melanomas.

Verruca Vulgaris

Verrucae vulgaris are common contagious warts associated with human papillomavirus type 1. They usually occur as hyperkeratotic

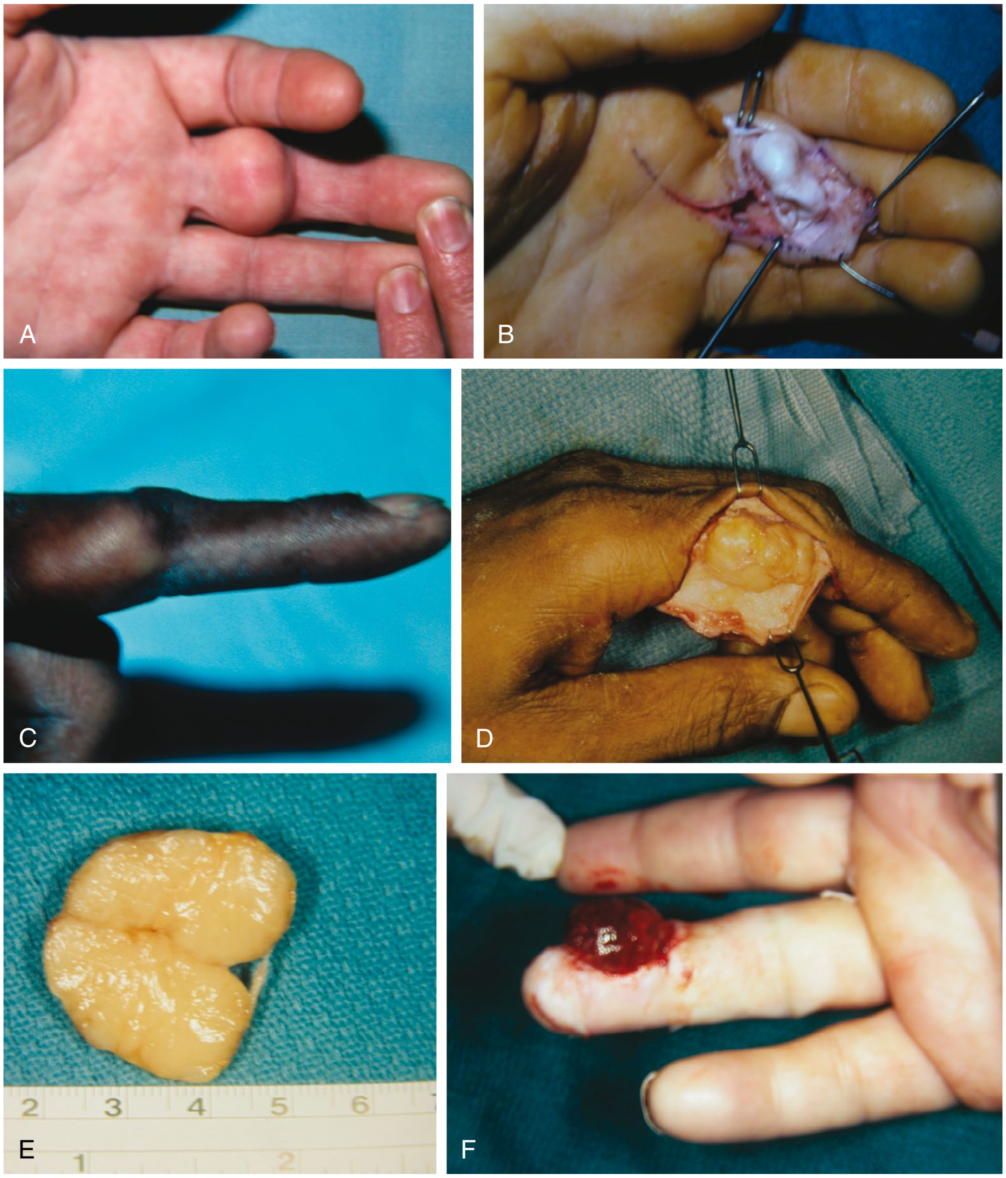

FIGURE 119.45 Soft tissue tumors of the hand. (A) Traumatically induced inclusion cyst on the palmar aspect of the middle finger in a manual worker. (B) Intraoperative photograph demonstrates cyst filled with toothpaste-like gel derived from keratin. (C) Firm, progressively enlarging swelling on the radial side of the left index finger. (D) Firm, lobulated, yellow-brown giant cell tumor insinuating onto the dorsal and volar aspects of the finger is noted intraoperatively. (E) Giant cell tumor is the most common solid soft tissue tumor encountered in the hand. (F) Fleshy, friable pyogenic granuloma bleeds easily on contact.

filiform lesions on the digits or around the nail bed. The most effective topical treatments are salicylates, liquid nitrogen cryotherapy, and especially curettage. Recalcitrant lesions respond to oral cimetidine given for 6 to 8 weeks and to imiquimod, an immunomodulator that increases interferon production. Their incidence, like that of squamous cell carcinomas, is increased in immunocompromised patients, such as in those after transplantation. Recurrence is relatively common.

Seborrheic Keratoses

Seborrheic keratoses are benign, hyperkeratotic, scaly lesions. They are frequently pigmented and common on the dorsum of the hand in older adults. Occasional confusion occurs with pigmented basal cell carcinomas. When necessary, these superficial scaly lesions are best treated by shave excision, and sutures are unnecessary. Rapid reepithelialization occurs.

Keratoacanthoma

Keratoacanthoma occurs on exposed body parts such as the dorsum of the hand. It grows rapidly over approximately 3 weeks into a nodule with a central umbilicated keratotic plug, often followed by spontaneous resolution in many weeks or months. The resulting scar is often worse than if the lesion had been excised initially. There may be diagnostic uncertainty in regard to well-differentiated squamous cell carcinomas. Hence, most authors recommend surgical excision.

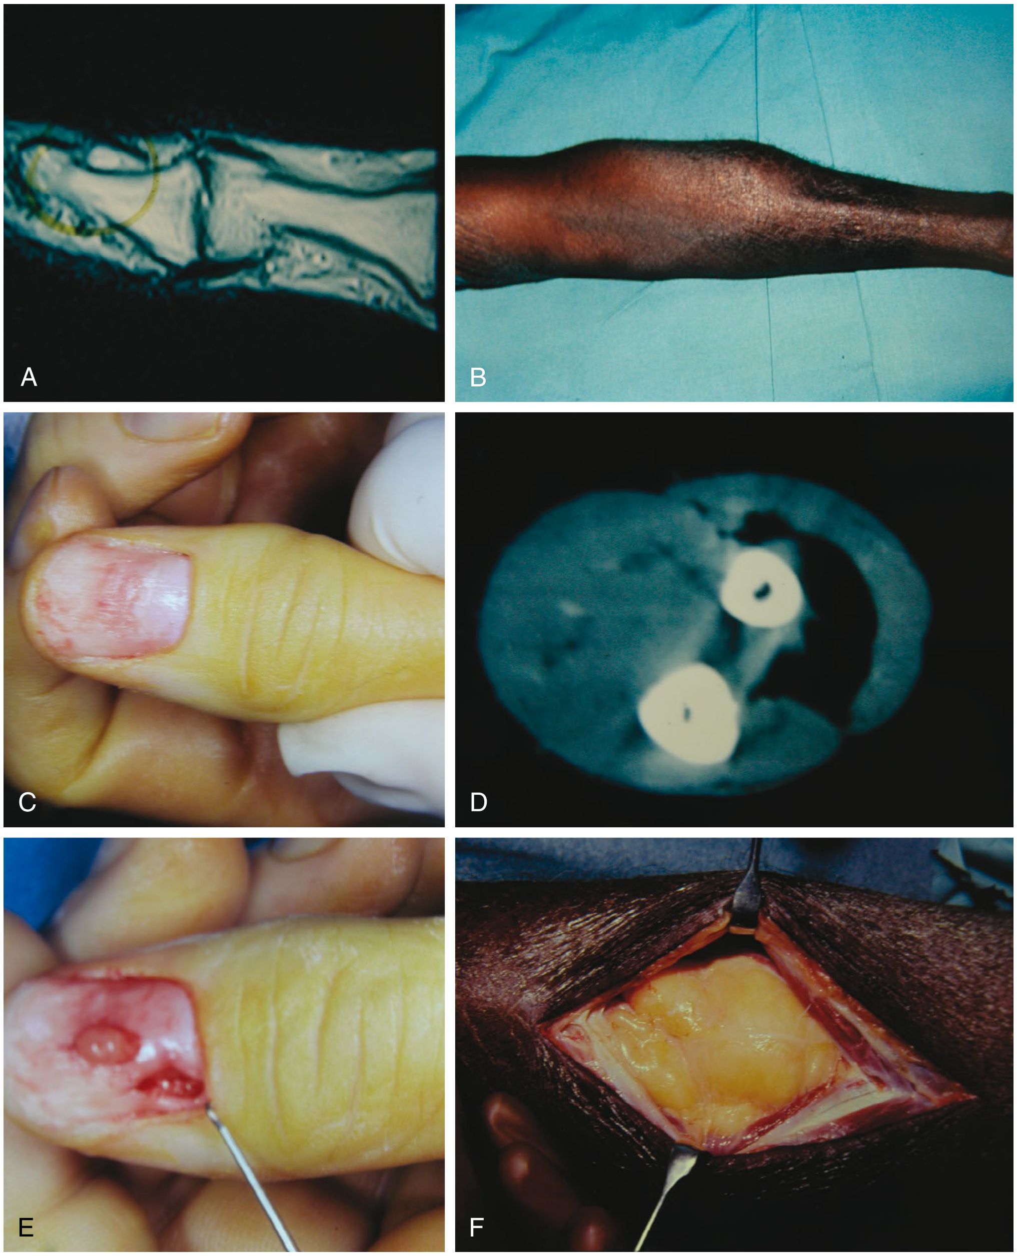

FIGURE 119.46 Soft tissue tumors of the hand. (A) Patient presenting with pain in tip of thumb, exacerbated in cold weather. Exquisite pain on palpation of the thumb nail plate is typical of a subungual glomus tumor that can be demonstrated by magnetic resonance imaging. (B) Occult subungual glomus tumor may be difficult to appreciate, even after removal of the nail plate, but it can often be identified by a surface bulge of the nail bed. (C) Excised glomus tumor sitting on nail bed. A nail bed defect requires repair with fine absorbable sutures. (D) Patient with swelling of left dorsoradial forearm and weakness of finger and thumb extension. (E) MRI reveals a dorsal forearm mass compressing the posterior interosseous nerve. (F) Dorsal approach over the mass reveals intramuscular benign lipoma when extensor muscles are split.

Dermatofibroma

A dermatofibroma arises from fibrous dermal tissue as a firm erythematous plaque, sometimes having central umbilication. It is often adherent to the overlying epidermis. Surgery is required primarily for diagnosis.

Vascular Malformations and Hemangiomas

Hemangiomas are hamartomas that are rarely visible at birth and are usually noticed weeks to months later. Rapid proliferation occurs in the first year of life. On histologic evaluation, proliferation of endothelial cells with increased mitotic activity is seen in conjunction with pericytes and dendritic and mast cells. Hemangiomas occur 10 times more commonly than vascular malformations, and approximately 70% involute by the age of 7 years, leaving a fibrofatty scar with redundant skin. Excision is seldom required and, after involution, is usually cosmetic. On occasion, oral or injectable steroids may be necessary to control rapidly proliferating lesions that cause pain or interfere with function.

Propranolol, which reduces basic fibroblast growth factor and vascular endothelial growth factor expression, is sometimes added in conjunction with steroids for problematic hemangiomas.[86,87]

By contrast, vascular malformations show normal endothelial growth characteristics and normal mast cell counts. They are often noted at birth, and growth is usually commensurate with the child for low-flow lesions. They do not undergo spontaneous involution.

Vascular malformations are subclassified into low-flow lesions; capillary, venous, and lymphatic lesions predominate. Arterial and arteriovenous fistulas predominate in high-flow lesions, and accelerated growth may occur relative to the patient. Pressure effects, ulceration, bleeding, and high-output cardiac failure can occur in severe cases. Enlarging lesions hinder hand function. Compression garments can provide symptomatic relief in some cases. Pain is often caused by vascular engorgement, phlebitis, or intralesional coagulation. D-dimer levels may be elevated, and some patients obtain relief from aspirin. Combined surgical excision and radiologic embolization are most effective in preventing recurrence caused by dilation of collateral vascular channels after simple excision.

Lymphaticovenous malformations may also be associated with generalized hypertrophy of an extremity. Vascular malformations and isolated macrodactyly are seen in Klippel-Trénaunay syndrome.

Malignant Skin Tumors

Basal Cell Carcinoma

Basal cell carcinoma is rare on the hand and is generally located on the dorsum. It is usually an ulcer with raised pearly edges. Treatment consists of excision with a margin of normal adjacent tissue. Nail bed lesions can be mistaken for paronychial infection, and amputation at the DIPJ may be required.

Squamous Cell Carcinoma

Squamous cell carcinoma may arise de novo from ultraviolet light exposure because of occupation or climate, usually on the sun-exposed dorsum of the hand. Approximately 16% of actinic keratoses may progress to squamous cell carcinoma. Arsenical keratoses may develop secondary to exposure to inorganic arsenic compounds but have a predilection for the palm.

Bowen disease is an intraepidermal squamous cell carcinoma (carcinoma in situ). It is a plaquelike lesion with crusting. Complete surgical excision with a margin of normal tissue is curative. When the nail matrix is involved, amputation at the DIPJ may be necessary.

For squamous cell carcinoma lesions smaller than 2.5 cm in diameter, wide excision with approximately a 6-mm clear margin is recommended. However, for larger lesions, more radical excision may be required, which may even include ray or segmental amputation for deeply adherent and invasive lesions. Mohs micrographic surgery and three-dimensional histologic reconstruction with a pathologist at the time of radical resection help ensure complete excision. Routine prophylactic lymphadenectomy is not beneficial. However, lymphadenectomy may be advised for recurrent tumors, even though lymph nodes may not be clinically palpable. Malignant degeneration may occur in cicatricial tissue and chronic ulcers (e.g., Marjolijn ulcer) and, in particular, in burn scars. Prognosis tends to be poorer.

Malignant Melanomas

Melanoma of the hand is cutaneous or subungual. There is an almost equal distribution of cases between the two types. Frequently, there is a delay in treatment, particularly with subungual melanomas. Suspicious lesions should be biopsied.[88]

Any subungual pigmented lesions should generally be biopsied. Under tourniquet control and with loupe magnification, the nail plate is atraumatically removed, and a longitudinal, elliptical, full-thickness excision of the lesion is performed. Careful nail bed repair is done after biopsy by the advancement of adjacent tissues and using fine absorbable sutures. The nail plate is then reapplied to act as a splint.[88]

Benign melanocytic hyperplasia, without evidence of atypia, is completely treated by this form of biopsy. If there is any evidence of melanocytic atypia, absolute confirmation of complete excision is required. In the absence of a clear margin or with recurrence of such a lesion, total nail bed excision and reconstruction with a full-thickness skin graft are required. Melanoma in situ is similarly treated. Invasive melanoma of the nail bed is treated by amputation at the next most proximal joint. Acral lentiginous melanoma of the palm may sometimes be mistaken for a wart, which may also delay diagnosis. These tumors are aggressively treated with wide local excision and potential sentinel node biopsy, just as they might be treated anywhere else on the body.[88]

Bone Tumor

Osteoid Osteoma

Osteoid osteoma may occur in the hand and classically causes pain that is worse at night and unrelated to use or motion of the hand (Table 119.10). Osteoid osteomas produce prostaglandins; symptoms are relieved by nonsteroidal antiinflammatory drugs (NSAIDs). On radiologic examination, a round, lucent tumor with sclerotic edges is seen (Fig. 119.47A). Conservative treatment with NSAIDs may be considered, but definitive treatment is surgical.

Aneurysmal Bone Cyst

Aneurysmal bone cyst is an expansile osteolytic bone lesion with a thin wall. It is usually derived from a preexisting bone tumor, usually a giant cell tumor (20%–40% of cases). Of these, 25% occur in the upper extremity, causing pain that peaks during 2 to 3 months. A bone swelling may be detectable, with increased overlying skin temperature.

Enchondroma

Enchondromas usually occur in the hand and are the most common bone tumor of the hand. Peak incidence is in the second decade, with equal sex distribution. They are frequently asymptomatic and noted incidentally as lytic lesions on plain radiology. Pain, bone swelling, or pathologic fracture may occur as these cartilaginous intraosseous cysts compromise bone structural integrity (see Fig. 119.47D). Treatment is by curettage and bone grafting of the osseous defect. Multiple enchondromatosis occurs in Ollier disease and is associated with angiomas in Maffucci syndrome.

Primary Bone Sarcomas

Primary bone sarcomas (malignant tumors) are rare in the hand.

Secondary (Metastatic) Bone Tumors

Metastatic tumors, even those with a tendency to metastasize to bone, usually occur in the axial skeleton and long bones. They are very rare in the hand.

CONGENITAL ANOMALIES

Congenital hand and upper extremity anomalies encompass a wide array of conditions. Their prevalence is ~1 in 600 live births. The causes of congenital hand anomalies may be genetic, teratogenic,

TABLE 119.10 **Bone Tumors of the Hand**

TUMOR	PRESENTATION	MOST COMMON LOCATIONS	TISSUE OF ORIGIN AND APPEARANCE	TREATMENT	RADIOGRAPHIC APPEARANCE
Enchondroma	Often incidental finding on routine hand radiograph; presents as pain secondary to pathologic fracture; most common bone tumor of hand	Proximal and middle phalanges and metacarpals	Fragments of cartilage nests; multiple (Ollier disease); when associated with hemangiomas (Maffucci syndrome), may undergo malignant change	Curettage, filling of defect with cancellous bone if structural bone integrity is compromised	Lesion eccentric in bone shaft with calcific stippling
Osteochondroma	Benign bone prominence (capped with cartilage); rare in hand; may cause angular growth and interfere with joint motion	Fingers and wrist; growth stops after skeletal maturity reached	Aberrant focus of cartilage; multiple osteochondromatosis is autosomal dominant; malignant change may occur	Surgery may be necessary, generally after epiphyseal closure	Exostosis, often at base of proximal phalanx; often shortening of parent bone
Osteoid osteoma	Aching pain, greatest at night, sometimes responding specifically to aspirin; patient may be labeled as malingerer	Phalanges, metacarpals, carpals	Nidus composed of loose fibrovascular connective tissue between bars of osteoid and bone trabeculae	Surgical excision to include the nidus	Very small lesion; some not seen on plain radiographs and require CT scan; cortical sclerosis surrounding a radiolucent area of nidus
Giant cell tumor of bone	Expansile bone swelling at distal radius or in phalanx	Distal radius most common site	May be locally aggressive and even metastasize	Curettage for low-grade lesions, but en bloc resection for high-grade lesions; do not irradiate because it could induce sarcomatous change	Expansile soap-bubble lesion in bone; high-grade lesions break through cortex

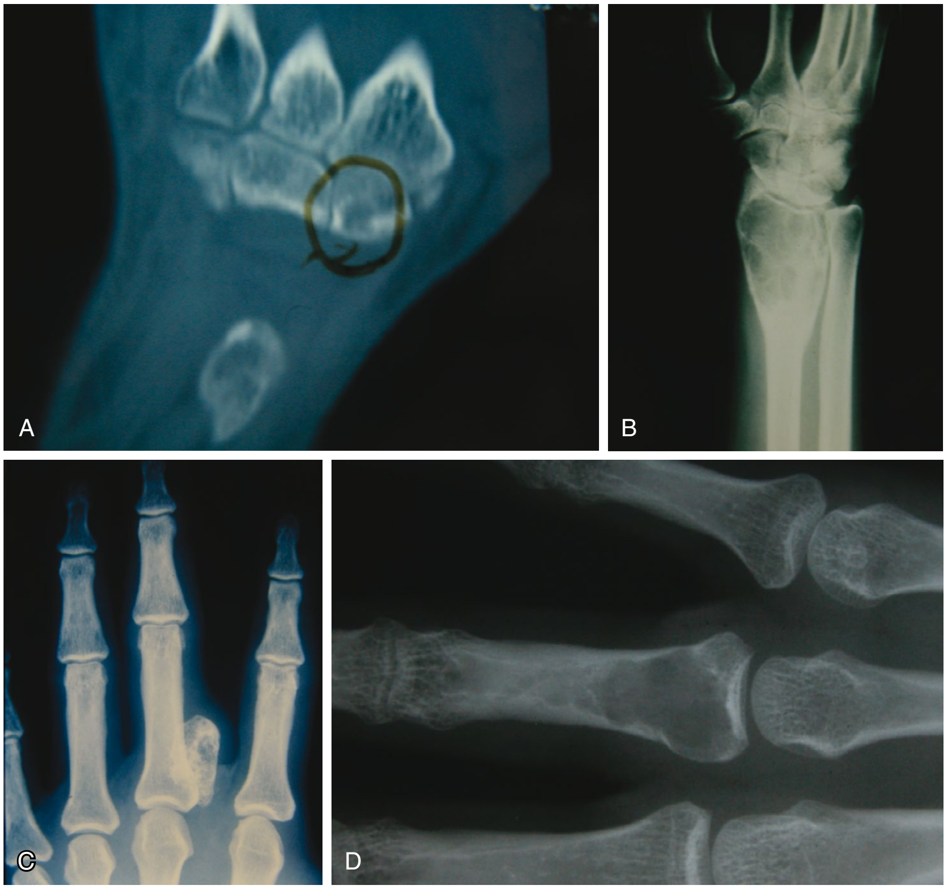

FIGURE 119.47 Plain radiographs of the upper extremity. (A) Osteoid osteoma of carpus. (B) Soap-bubble appearance of giant cell tumor expanding the metaphysis of the distal radius. (C) Osteochondroma of proximal phalanx of middle (long) finger. (D) Patient with finger pain after trivial injury. This is a pathologic fracture of the base of the proximal phalanx through an enchondroma that has replaced most of the proximal metaphysis and medulla.

or idiopathic and may also have a syndromic association with anomalies elsewhere in the body. Knowledge of these associations is important because the more life-threatening associated problems frequently need to be treated first, before the hand and upper extremity reconstruction can be performed. Such an association is found in a constellation of problems that occur in the VACTERL association of congenital defects (vertebral anomalies, anal atresia, cardiac abnormalities, tracheoesophageal fistula, renal agenesis, and limb anomalies).

A number of factors must be considered in optimizing the timing of each surgical procedure to the upper extremity, including the psychosocial development of the child, presence of other illnesses, size of the structures to be operated on, and normal growth and development of the hand. Modern technologic advances have allowed us to operate on smaller structures; the timing of the procedure can now be guided by knowledge of the anatomy and development of the growing hand. Optimal function is the primary goal of surgery. Early surgery prevents the emotional scarring associated with a child's awareness of the deformity, and some congenital problems may not be apparent in the neonate. The hand surgeon must work closely with the pediatrician to identify general conditions that may affect the child's health. Some congenital anomalies of the extremities, especially those with the radial ray, may be associated with bone marrow failure (Fanconi syndrome) or heart defects that may not be immediately apparent in the neonate. Children with congenital anomalies will attempt to keep up with their peers and often develop successful hand substitution techniques. However, once a child experiences the cruel ridicule of playmates or the unintentional but sometimes overly solicitous supervision of a teacher, the deformity becomes important. In general, plans for surgical reconstruction are designed to be completed by school age so that the child may adapt to and fully use the reconstructed limb.[89,90]

The rationale for early surgery includes the avoidance of deformity and malfunction and optimal use of infantile tissue plasticity. Because hand length almost doubles during the first 2 years of life, a digit tethered to another digit that fails to grow can produce a major deformity during the early growth spurt. For example, with separation of syndactyly that involves the border digits of the hand, because of adjacent tethering to a digit of unequal length, surgical separation of the syndactyly is required at an early age, as early as 6 months, to avoid secondary angular deformity of the digits.

In rare circumstances, urgent treatment in the neonate is required. The distal lymphedema of a severe constriction band syndrome may be so marked as to inhibit function totally or even threaten distal viability. This may require urgent release. The unusual clinical entity of aplasia cutis may result in exposure of vital structures, requiring urgent soft tissue coverage, even in the neonatal period.

Early operation, although not urgent, may be required not only because of the rapid growth that occurs in the first 2 years of life but also because of functional consequences. Surgery at a young age is considered mandatory in children with malformations in which hand function may be altered by surgery or in those who are at risk for development of certain grasping habits that would have to be unlearned after corrective surgery. An older child, 12 to 14 years of age, has developed grasp patterns that would have to be altered by prolonged periods of physical therapy after corrective surgery.[86]

The ability to place the upper limbs in space (a cortical function) and development of a strong grasp are established by 1 year of age, as are grasp and pinch maneuvers between the thumb and fingers. Accuracy of prehension and refinement of coordination continue until 3 years of age. Surgery must be performed early to allow the affected parts to develop differently when the function of the parts of the hand is altered by transposition (e.g., pollicization of an index finger for thumb aplasia). Duplicated thumb correction is carried out before 1 year of age, well in advance of the development of integrated thumb grasp patterns.

Finally, the physical ability of infant bone and soft tissues to adapt to change produced by surgery is also a key factor in deciding when to operate. In the early pollicization of the index finger, the first dorsal interosseous muscle hypertrophies to form a thenar eminence, and the first metacarpal (formerly known as the *proximal phalanx* of the index finger) broadens. If centralization of the wrist for radial dysplasia (formerly known as *radial club hand*) has been undertaken early, the head of the ulna broadens to resemble the distal end of the radius.

Thus, a number of issues are taken into consideration when deciding on the optimum time for surgical reconstruction of congenital hand and upper extremity anomalies. The more common hand anomalies include syndactyly, polydactyly, constriction band syndrome, and absent or hypoplastic thumb.

Syndactyly results from the failure of programmed cell death (apoptosis) between the individual finger rays. Consequently, there is a resulting fusion of adjacent digits. It can involve part or all of the length of the digits (incomplete or complete) and may be limited to skin and soft tissue only (simple syndactyly) or can also involve skeletal fusion (complex syndactyly). Apert syndrome also involves craniofacial anomalies and is a severe form of bilaterally symmetric complex syndactyly. Surgical treatment involves digit separation using a local flap to reconstruct the depths of the commissure between the fingers and release of the finger borders with zigzag incisions and the use of full-thickness skin grafts (Fig. 119.48A).

Polydactyly is the presence of extranumerary digits on the hand. Preaxial (radial) polydactyly involves the thumb. It is not as common as postaxial (ulnar) polydactyly, which is the most frequent congenital hand anomaly in African Americans. Polydactyly can be as simple as the presence of a skin tag–like structure or may have a complex arrangement of shared vessels, nerves, and bones. Thumb polydactyly is not merely a duplication but a splitting of a single digit, with variable degrees of development in each of the separate parts. It is typically classified into seven subtypes by the Wassel classification, which is based on the specific duplication, progressing from distal to proximal, in which the odd numbers are at distal and proximal phalanx and metacarpal, and even numbers are at IPJs, MPJs, and CMCJs, respectively. Type IV is the most common type, with total duplication of proximal and distal phalanges and a shared MPJ. Type VII refers to associated triphalangia with a duplication. Reconstructive goals include stabilization without sacrificing mobility, proper alignment of joints along the longitudinal axis of the thumb, balanced motor units, and a cosmetically acceptable nail plate (see Fig. 119.48B–C).

The Blauth classification categorizes thumb hypoplasia from type I, which represents minor hypoplasia, to type V, which is a total thumb absence. Surgical correction ranges from reconstruction of the existing hypoplastic thumb to pollicization (creating a thumb from the index finger) for complete absence or for the more severe types of hypoplasia (Fig. 119.49).

Clinodactyly is a curving of the digits in a radial or ulnar direction. It is common, particularly involving the little finger in many individuals, but a curvature of more than 10 degrees is considered abnormal. The distal phalanx is usually affected, and a delta phalanx may be associated. A delta phalanx occurs when the epiphysis forms a *C* shape around the metaphyseal core in the middle phalanx. Most patients present with little or no functional or

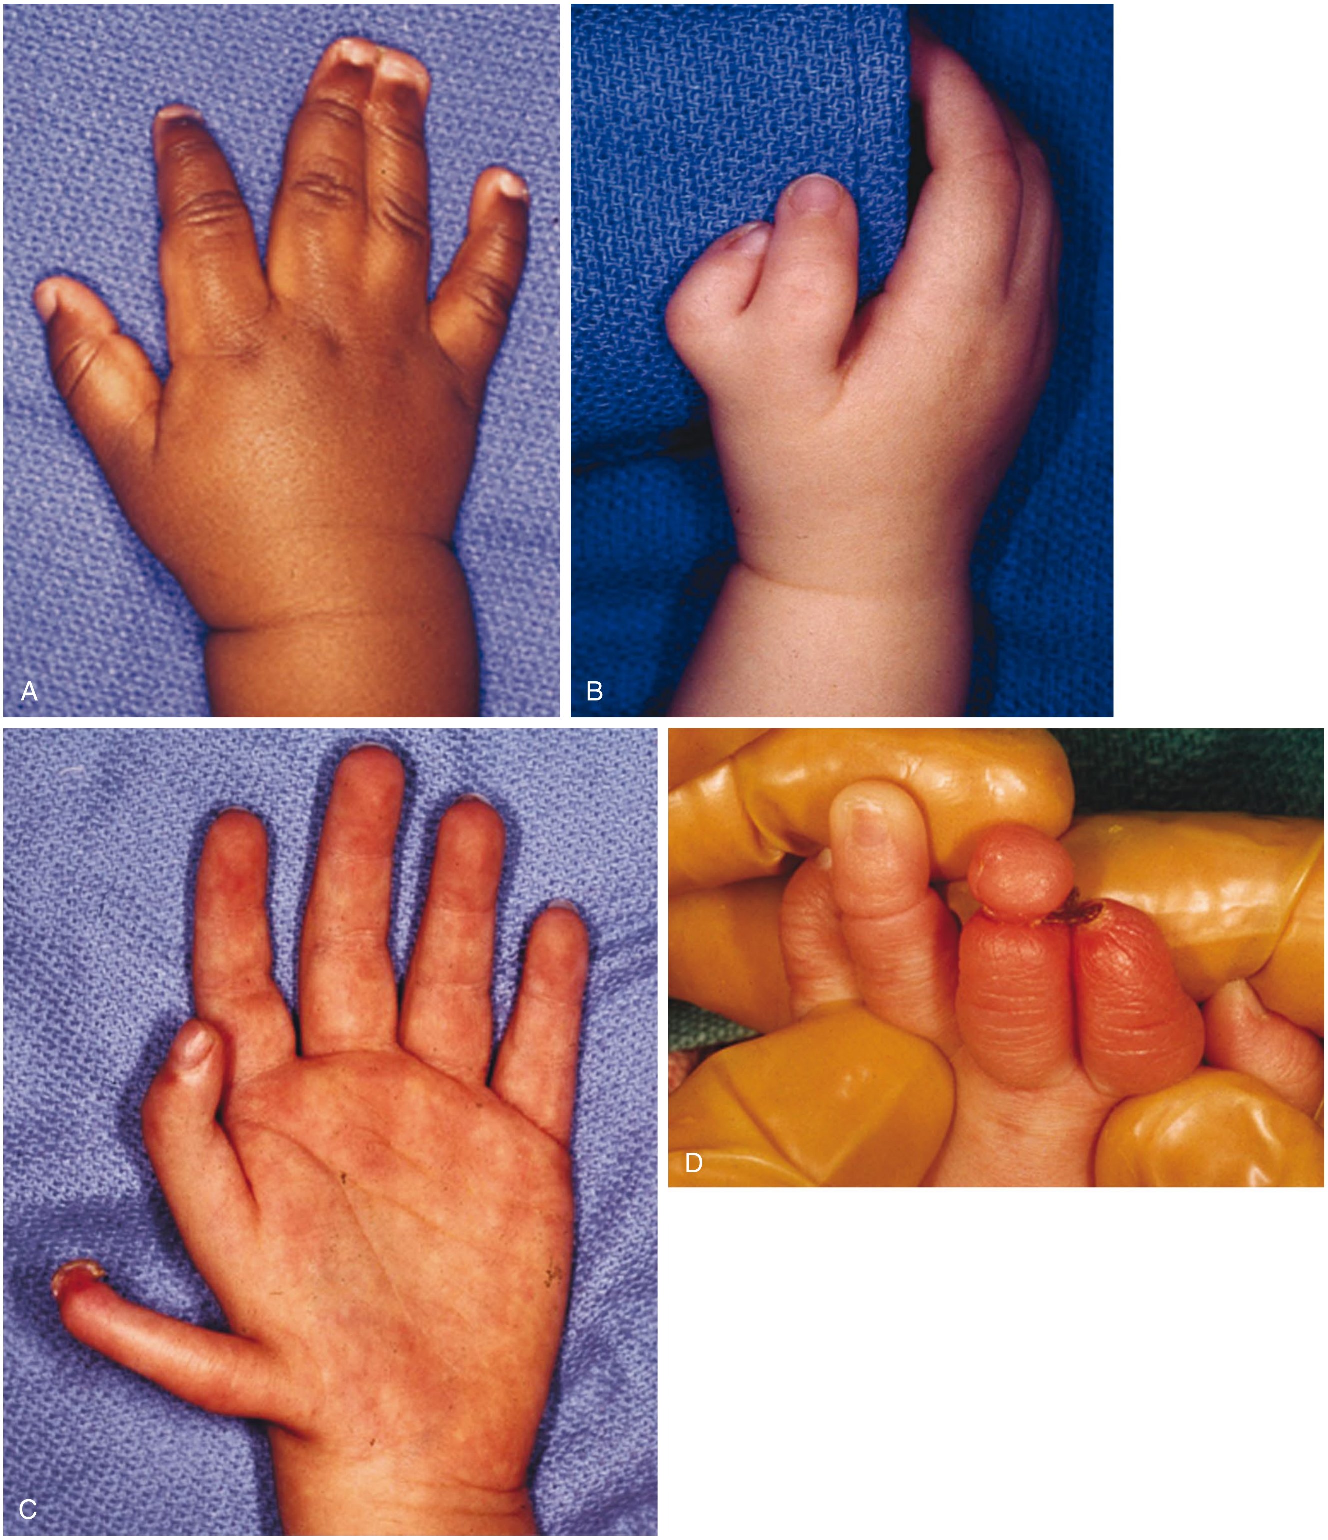

FIGURE 119.48 Congenital hand anomalies include syndactyly (A), Wassel type IV thumb polydactyly (B), Wassel type VI polydactyly (C), and constriction band (D).

cosmetic deformity, and operative intervention is seldom required. If there is a functionally impairing deviation of the finger, corrective osteotomy can be done.

Camptodactyly is a congenital flexion deformity of digits. It usually occurs in the little finger PIPJ. The exact cause is unclear, but it has been attributed to a variety of different structures around the PIPJ, including a skin pterygium, collateral ligaments, volar plate, flexor tendon, abnormal insertions of lumbrical or interosseous muscles, and size and shape of the head of the proximal phalanx. Treatment is generally nonoperative and may involve serial splinting. If no improvement occurs and the flexion deformity is sufficient to cause a functional problem, surgical

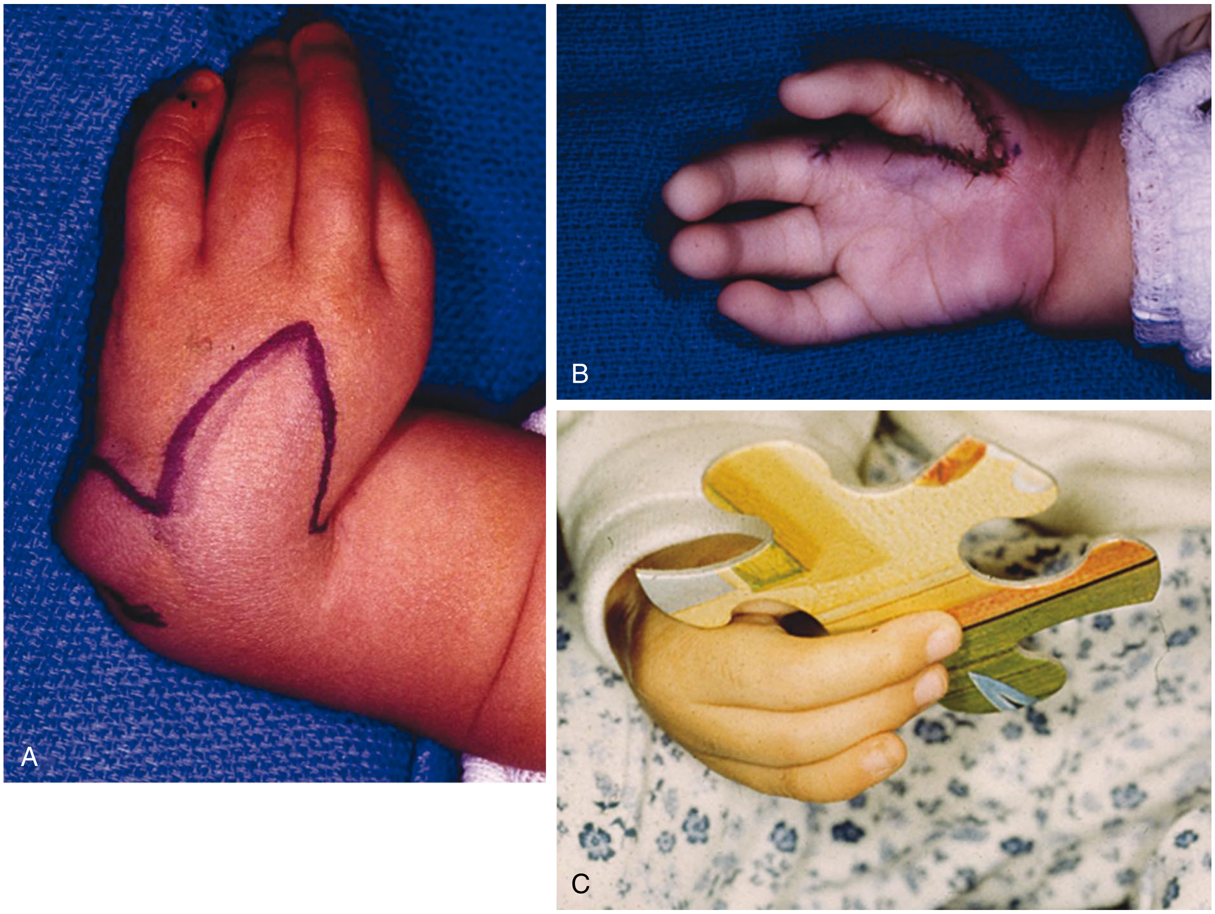

FIGURE 119.49 Clinical photos demonstrating a patient with radial longitudinal deficiency and absent thumb. Patient underwent a centralization procedure using a bilobed flap (A) and pollicization of the index finger, creating a thumb (B–C).

intervention may be required; this includes correction of the deformity with Z-plasty and possibly grafts. One author has reported that all his patients who had reconstructive surgery on one hand did not ask for corrective surgery on the opposite affected hand.

Constriction band syndrome is secondary to intrauterine amniotic bands (see Fig. 119.48D). These can act like tourniquets and threaten the viability of digits and even limbs, resulting in congenital amputation. Infants may suffer from a similar problem from the external ligature effect of cotton strands coming off protective booties and even from a human hair, termed the *hair-thread tourniquet syndrome.*

OSTEOARTHRITIS AND RHEUMATOID ARTHRITIS

Osteoarthritis may be primary or posttraumatic (secondary). Primary osteoarthritis is a degenerative joint disease occurring in later life. An injury that leaves articular surfaces of a joint incongruous can precipitate secondary osteoarthritis. Osteoarthritis begins with biochemical alteration of the water content of articular cartilage. The cartilage weakens and develops cracks, called *fibrillation.* Progressive erosion and thinning of the cartilage result, and the subchondral bone becomes sclerotic, termed *eburnation.* New bone forms around the edges of the articular cartilage, and these outcroppings are called *osteophytes* (Fig. 119.50).

The joints usually affected in the hand are the DIP and PIPJs of the fingers and carpometacarpal joint at the base of the thumb. Osteophytes at the DIPJ are called *Heberden nodes,* and those at the PIPJ are known as *Bouchard nodes.* The involved joints may be painful, stiff, deformed, or subluxated. Radiographs reveal narrowing of the joint space, sclerosis of subchondral bone, and presence of osteophytes.

Initial treatment may be symptomatic and may include splinting and even local corticosteroid injections. NSAIDs may be helpful, and chondroprotective medications such as glucosamine and chondroitin sulfate can reduce symptoms. In advanced cases, the DIPJs respond best to arthrodesis. The PIPJs may be surgically treated by replacement arthroplasty or by arthrodesis (Fig. 119.51). The thumb carpometacarpal joint may be treated by arthrodesis, which is favored particularly for the young patient who might have posttraumatic arthritis after, for example, an improperly treated Bennett or Orlando fracture. In an older patient with primary osteoarthritis at the thumb base, excision of the trapezium followed by tendon suspension (interposition) arthroplasty may be preferred. This uses local tendons for construction of a sling arthroplasty, with interposition of tendon material.

Rheumatoid arthritis is an autoimmune process whereby destruction of the musculoskeletal system may occur. Synovial inflammation results in pain, joint destruction, tendon ruptures, and characteristic deformities. Some of the more common deformities associated with rheumatoid arthritis include a swan-neck

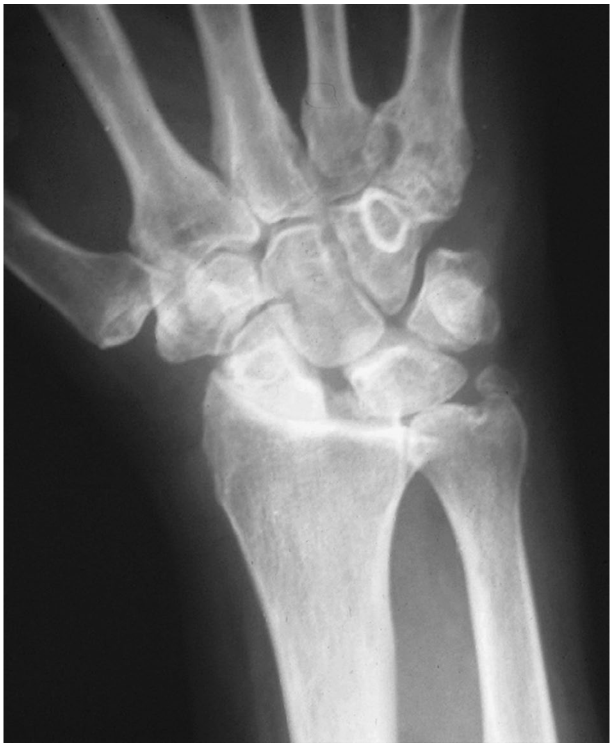

FIGURE 119.50 Radiograph of a hand with a scapholunate advanced collapse wrist showing posttraumatic osteoarthritis at the radioscaphoid junction. This is many years after a wrist sprain in which the scapholunate ligament was torn; a wide scapholunate gap is visible on the radiograph.

deformity (hyperextension of the PIPJ with concurrent flexion at the DIPJ), boutonnière deformity (flexion at the PIPJ, with concurrent hyperextension at the DIPJ), joint subluxation, radial deviation of the wrist, and ulnar deviation and flexion of the fingers (Fig. 119.52). Rheumatoid arthritis is primarily a medical illness for which several medications are currently available. Thus, there must be excellent lines of communication between the rheumatologist and surgeon. NSAIDs and disease-modifying antirheumatoid drugs are used. Rheumatoid arthritis is a progressive disorder, and ongoing, slow destruction may be anticipated despite surgery (Fig. 119.53). Some of the more common surgical procedures include joint synovectomy, tenosynovectomy, tendon transfers, joint replacements (especially at the MPJs and PIPJs), and arthrodesis (more commonly at the wrist and thumb MPJ).[91]

CONTRACTURES

Volkmann ischemic contracture develops as a result of myofascial contractures in response to prolonged ischemia. This most common contracture results from untreated compartment syndrome of the forearm and hand. Muscle necrosis occurs, and the muscles become replaced by fibrous scar tissue. The FDP and FPL muscles are usually affected, being in the deepest forearm volar compartment, and digits are characteristically flexed, with passive extension of the wrist worsening the flexion deformity of the digits. Intrinsic contractures can occur in the hand; these can be investigated using the Bunnell test, in which passive extension of the MPJ makes passive flexion of the PIPJ more difficult.

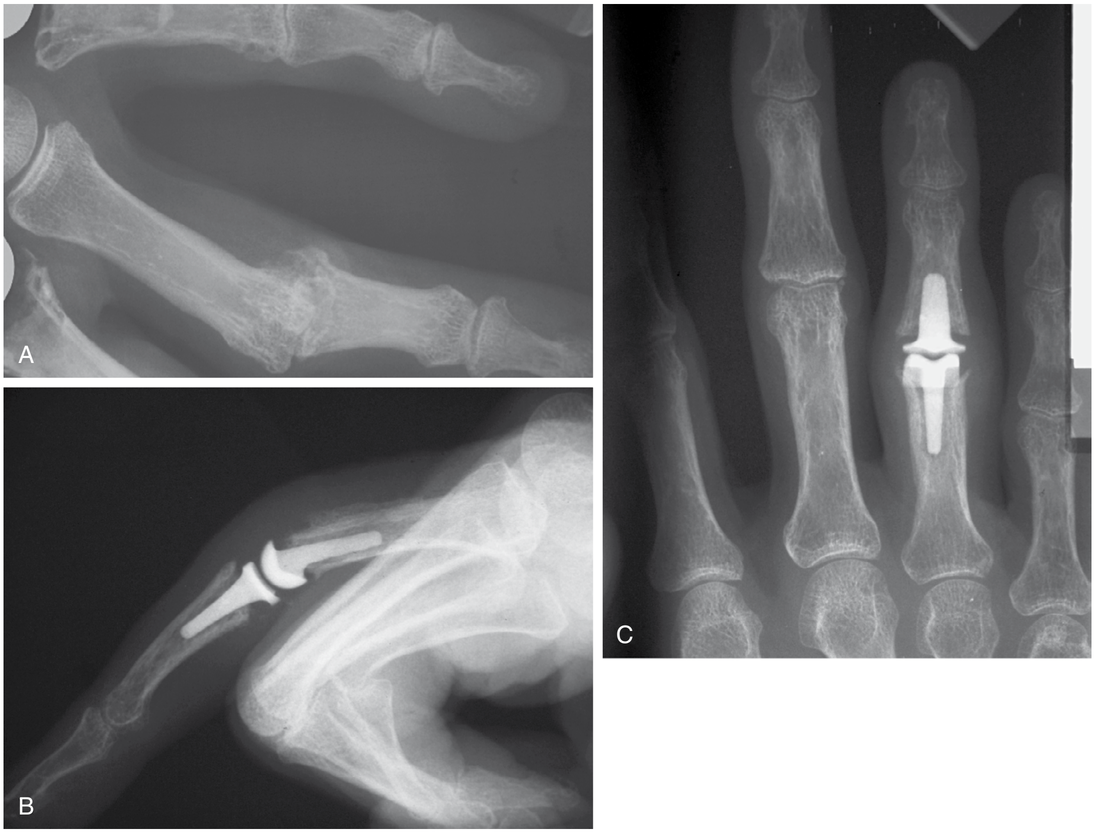

FIGURE 119.51 (A) Patient with painful and unstable proximal interphalangeal joint from osteoarthritis. (B–C) Reconstruction is performed by implant arthroplasty. An advantage over arthrodesis is that motion is retained, although there remains the potential for future recurrent joint instability and wear of the artificial joint.

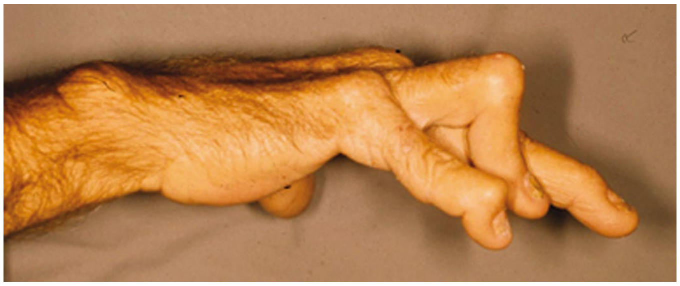

FIGURE 119.52 Patient with inflammatory arthritis has both boutonnière deformity and swan-neck deformity on the same hand.

In the milder forms of Volkmann ischemic contracture, serial splinting and passive stretching exercises may resolve the problem. In more severe contractures, Z-type lengthening of tendons may be required. A flexor pronator muscle slide—subperiosteal elevation of the common flexor origin from the medial epicondyle of the humerus and from the ulna—allows the muscles to slide distally until the contracture is corrected. In the most severe form, all the muscles of the volar forearm may be affected, requiring tendon transfers, even microvascular functional muscle transfers to provide some functional return.

Posttraumatic contractures are the most common type of contracture. These can be prevented by appropriate treatment of the primary injury, especially with attention to detail in how the hand and upper extremity are splinted and immobilized. Once contractures have developed, if they are mild, they may be able to be stretched out by exercises and hand therapy. If these contractures are severe and functionally deforming, surgical release of joint contractures and release of tendon adhesions may be required.

Dupuytren contracture is a disease process of contracting collagen affecting the palmar fascia; it can also affect the dorsum of the fingers (knuckle pads), soles of the feet, and penis (Peyronie disease). It is thought to be a hereditary Mendelian dominant disorder and is bilateral in 65% of cases. It is six times more frequent in males and predominantly involves the ring and little fingers (Fig. 119.54).

The process of Dupuytren contracture occurs in the normal bands of collagen tissue that form the palmar fascia, natatory ligaments, and digital sheaths. Nodules containing myofibroblasts and immature collagen (type III) develop in these tissues or in the dermis. The nodules progressively increase in size, leading to thickened contractures and shortened fascial bands that develop into cords extending up the digits. Treatment is surgical excision; it is indicated in metatarsophalangeal (MP) contractures of 30 degrees or more, when the patient fails the so-called tabletop test and cannot place the palm of the hand flat on a surface, and whenever there is a PIPJ contracture. Careful surgical technique is necessary to avoid complications such as skin necrosis, hematoma, and digital nerve injuries. Collagenase injections using enzyme derived from *Clostridium histolyticum* have been attempted

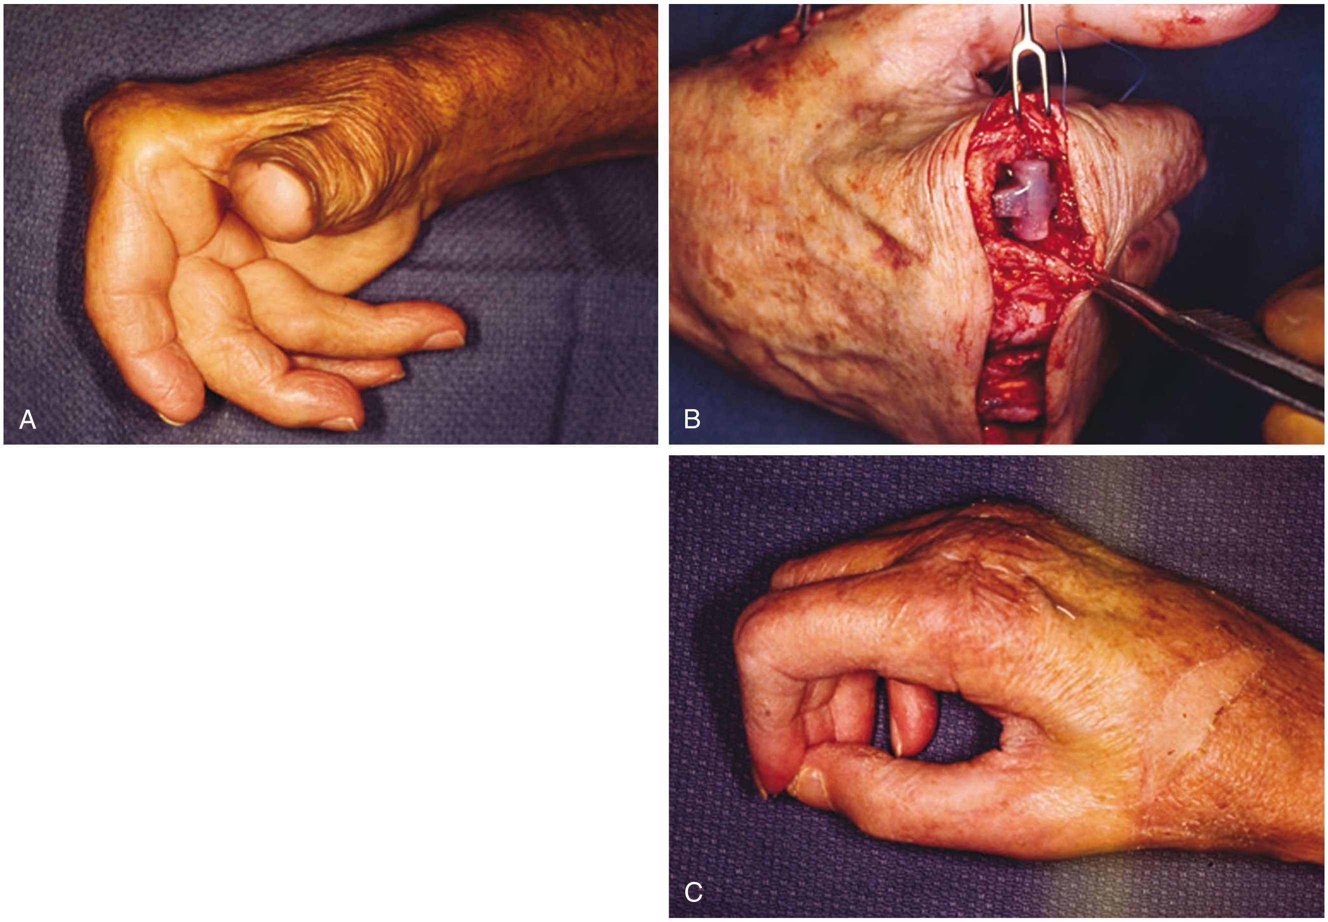

FIGURE 119.53 (A) Patient with rheumatoid arthritis showing the characteristic finger deformities. (B–C) Implant arthroplasty at the metacarpophalangeal joints restores function and aesthetics to the hand.

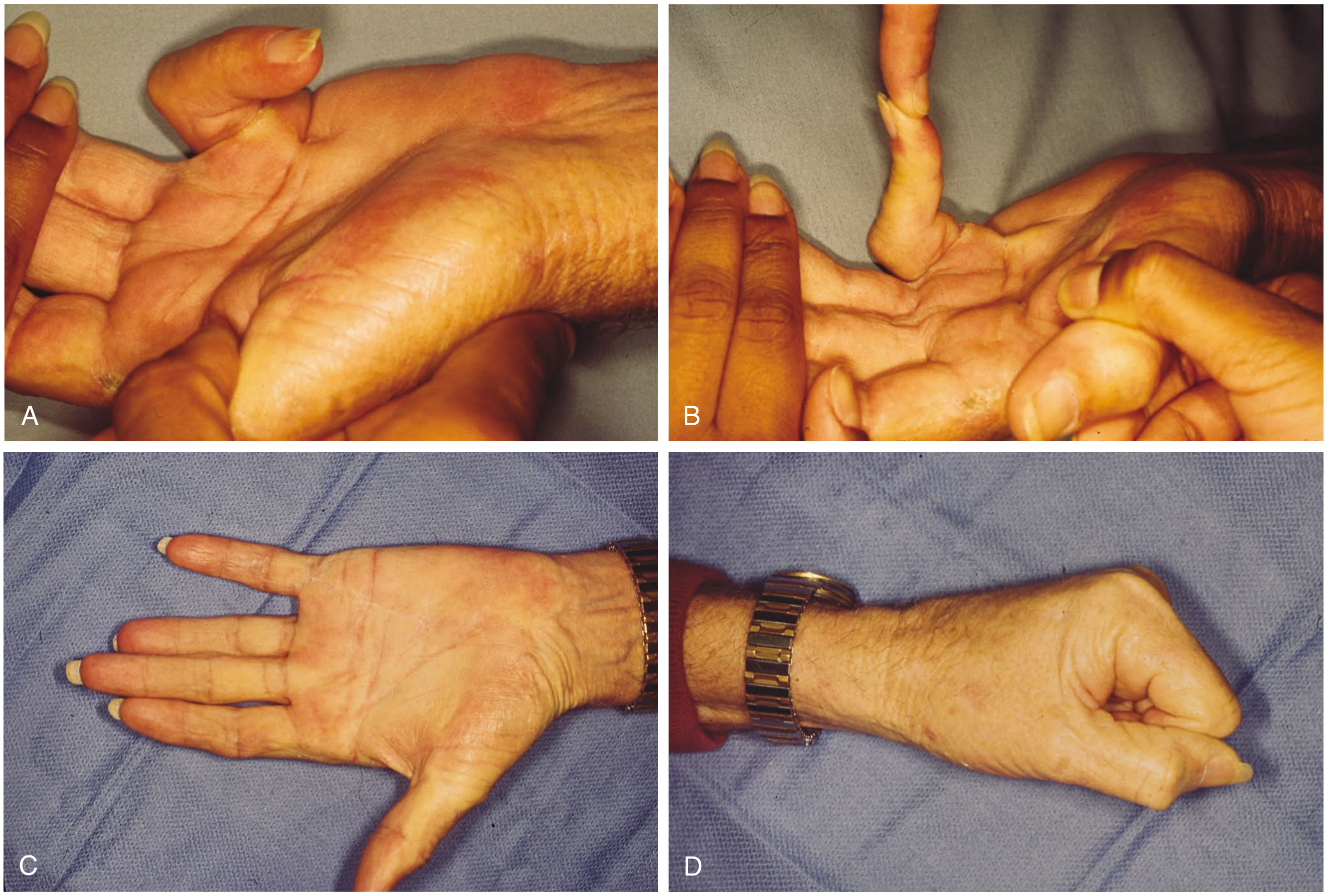

FIGURE 119.54 (A–D) Patient with Dupuytren's contracture is treated by regional palmar and digital fasciectomy, and good hand function is restored.

and have shown some promise in the treatment of Dupuytren contracture. However, long-term follow-up in patients who had these injections is still necessary.[92,93]

Percutaneous needle fasciotomy is also a reasonable option for treatment of Dupuytren disease and seems to be effective for MPJ contractures but less effective for the PIPJ. An extension external fixation torque device may also preliminarily reverse the PIP contracture before excision of the diseased tissue.[94]

FUTURE DIRECTIONS IN HAND SURGERY

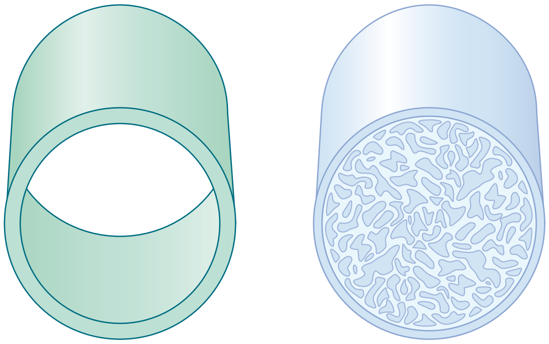
Hand surgery is a very dynamic specialty and is continually advancing, with many recent technologic developments. Because it is a regional specialty, it embraces advances in microvascular and microneural surgery, trauma, transplantation, minimally invasive surgery, prosthetics, and tissue engineering.

Methods of treatment of forearm amputation remain an ongoing debate between transplantation and prosthetic limbs. Dr. Joseph Murry, a plastic surgeon, performed the first successful kidney transplant in 1954. Hand transplantation has been refined by plastic hand surgeons, and as of 2021, there were 150 documented successful upper limb transplants around the world.[95] Functional outcomes must be balanced against the lifetime risks of immunosuppression.[95]

In contrast, there have been major advances in the field of prosthetics—specifically, improvements in prosthetic motor control secondary to TMR and regenerative peripheral nerve interface (RPNI). In TMR, transected nerves from the amputation are attached to individual motor nerves in the muscle that in turn transmits the myoelectric impulses to the various prosthetic functional movements. The prosthetic limb can "sense" the intended movements in the reinnervated muscles and move in the way that the patient intends it to move. An outreach of this research is also that TMR helps successfully treat phantom and neuroma pain. RPNI is a newer development where transected nerves are redirected to free muscle grafts to rennervate the tissue and therefore provide myoelectric signals that can be placed near the skin surface for easier capture.[96] The debate between prosthetics and transplantation will closely mirror the race between prosthetic technology and immunosuppression.

There has also been great interest in the development of ways to bridge nerve gaps in traumatic and oncologic reconstruction. The gold standard has been to use an autologous nerve graft, but this option has donor morbidity, and there is a limited supply available (generally sural nerve). Treated cadaveric nerve allografts remove the immunogenicity and may enable nerve reconstruction without donor morbidity.

Up to this time, nerve conduits have been merely a tube that guides the growth of axons to the distal nerve, which may be suitable for small nerves in the hand. However, nerve allografts contain the full scaffold of nerve, which allows for greater guidance of axonal growth. Autologous autografted nerves also contain Schwann cells and growth factors that, in theory, should help increase axonal growth and the "take" of nerve grafts. At this time,



Nerve conduit has no internal structure

Allograft has an internal microstructure

FIGURE 119.55 Nerve conduits versus nerve allografts.

it is uncertain what length of major peripheral nerve is best treated with an autograft versus an allograft (Fig. 119.55). Recent studies support the use of processed nerve allografts in sensory nerves up to 25 mm, but there is still heated debate regarding the use of allograft in larger gaps and in mixed/pure motor nerve reconstruction.[97]

There are many other advancements in implant technology, minimally invasive surgery, and tissue engineering, but those regarding transplantation, prosthetics design, and nerve repair are especially exciting and are coming to clinical fruition.

CONCLUSION

The specialty of hand surgery is exhaustive, and a number of specialty textbooks are available. Although general surgeons may be responsible for the basic tenets of hand surgery, knowledge of minute details is often not necessary; thus, most details have been omitted from this chapter because its purpose is to show the big picture in regard to hand surgery. Those topics of hand surgery that the general surgeon is most likely to encounter have been emphasized, particularly with regard to principles of anatomy, physical examination, and emergency treatments. Taking this into consideration, Table 119.11 includes some high-yield facts relevant to hand surgery that have been compiled from various general surgery review books as well as topics discussed in the American Board of Surgery In-Training Examination (ABSITE).[98,99] This list is provided for the convenience of general surgeons preparing for ABSITE or board examinations.

TABLE 119.11 American Board of Surgery Review Topics

TOPIC	ANSWER
Fracture of the distal radius	Injury to the median nerve
Innervation of flexor digitorum profundus to the ring and small fingers	Ulnar nerve
Injury to the ulnar nerve at the elbow	Weakness in abduction and adduction of the index finger through small digits
Midshaft humeral fracture	Associated with radial nerve injury
Distal phalanx fractures	>50% of all hand fractures
Joint involved in Bennett fracture	Carpometacarpal joint of the thumb
Common name for metacarpal fracture of the small finger	Boxer fracture
Most frequently fractured carpal bone	Scaphoid
Complications associated with displaced fractures	Avascular necrosis and nonunion of the scaphoid
Axonal nerve growth rate	1 mm/day
Common maximum intraoperative tourniquet time in hand surgery	2 hours
Single digits that are primarily replanted	Thumbs in adults and children, all digits whenever possible in children
Maximal period of anoxia compatible with replantation	Finger—8 hours (warm ischemia), but longer times have been anecdotally reported; upper and lower extremity—6 hours
Proper method for transportation of an amputated body part to maximize replantation success	Cleaned of debris, wrapped in sterile towel or gauze, moistened with sterile lactated Ringer solution, placed in sterile plastic bag, transported in insulated cooler with ice water (ideal temperature, 4°C)
Complications if nerve repair is delayed >2 weeks	Retraction of nerve's ends resulting in need for nerve grafting
Zone 2, no man's land	Area of flexor tendon injury between metacarpophalangeal joint and flexor digitorum superficialis insertion
Mallet finger	Injury to extensor mechanism at level of distal interphalangeal joint
Gamekeeper thumb	Rupture of ulnar collateral ligament of thumb metacarpophalangeal joint, with resultant instability of the joint to radial-directed force
Most common organism causing hand infections	*Staphylococcus aureus*
Classic symptoms of carpal tunnel syndrome	Paresthesias in median nerve distribution, often waking the patient at night
Most effective therapy for full-thickness burns of the hand	Early excision and grafting
Most common location of ganglion cysts	Scapholunate interosseous ligament at the dorsal wrist
Treatment of de Quervain stenosing tenosynovitis after failed nonoperative management	Surgical release of first extensor compartment
Cause of trigger finger	Stenosing tenosynovitis in the region of the metacarpophalangeal joint, A1 pulley
Late findings of rheumatoid arthritis	Subluxation of involved joints resulting in deformity
Swan-neck deformity	Hyperextension of proximal interphalangeal joint with flexion of distal interphalangeal joint

TABLE 119.11 American Board of Surgery Review Topics—cont'd

TOPIC	ANSWER
Boutonnière deformity	Flexion of proximal interphalangeal joint with hyperextension of distal interphalangeal joint
Nonoperative measures for Dupuytren contracture	Exercise, local steroid injections, collagenase injections, radiotherapy
Digits usually affected in Dupuytren contracture	Ring and small fingers
Cause of Dupuytren contracture	Proliferation and fibrosis of the palmar fascia
Fractures likely to cause compartment syndrome, Volkmann ischemic contracture	Supracondylar fracture of the humerus
Artery and nerve compromised in Volkmann ischemic contracture	Median nerve and anterior interosseous artery
Complication of cast placement for supracondylar fractures of the humerus	Volkmann ischemic contracture

Summary

Please access Elsevier eBooks+ to view the videos for this chapter.

Gynecologic procedures are among the most frequent surgical procedures performed in the world. It behooves any surgeon to be familiar with the anatomy of the female reproductive tract and pelvis and with the most common gynecologic surgical diseases and procedures for these diseases. This chapter provides an overview of pelvic anatomy in the female reproductive tract; discusses the most common disorders of the vulva, vagina, cervix, uterus, fallopian tubes, and ovaries; and reviews surgical procedures for these disorders. Principles of gynecologic surgical care for gender-diverse individuals are also reviewed. This foundational knowledge should provide surgeons with confidence to offer surgical interventions in a skillful and compassionate manner.

FEMALE REPRODUCTIVE AND PELVIC ANATOMY

Key components of the female reproductive tract anatomy include external reproductive anatomy (vulva) and internal reproductive anatomy (vagina, cervix, uterus, fallopian tubes, and ovaries).[1] Other relevant pelvic anatomy components include anatomic spaces, vascular and neurologic structures, and urologic and intestinal structures.[1] The following section provides an overview of these key components.

External Female Reproductive Anatomy (Vulva)

The main external structures of the vulva are the mons pubis, the labia majora and labia minora, the clitoral glans and clitoral hood, the urethral meatus, the vaginal introitus and hymen, and Bartholin and Skene vestibular glands (Fig. 120.1). The mons pubis is the soft fatty tissue covering the pubic bone. The lower part of the mons pubis is divided by a fissure named the pudendal cleft, which separates the mons pubis into the labia majora. The labia majora and labia minora are separated by a groove called the *interlabial sulci*, and the labia minora fuses anteriorly to form the clitoral hood (also known as the *prepuce*) and posteriorly to form the vestibule.

The vestibule is the area of the vulva consisting of the vaginal introitus, which is initially outlined by the hymenal ring, and urethral meatus. The vestibule is demarcated from the external vulvar structures by Hart's line. The anterior and posterior boundaries of the vestibule are the frenulum of the clitoris and the posterior fourchette, respectively. At the posterior vestibule, there is a small depression of tissue called the fossa navicularis where the Bartholin glands open. The Bartholin glands, homologues of the bulbourethral glands in males, are located posteriorly to the right and left of the vaginal introitus. Skene glands, homologues of the prostate gland in males, are located to the right and left of the urethral meatus. Both Bartholin's and Skene's glands produce secretions that provide vaginal lubrication.

The perineum is divided into the anterior and posterior triangle by a line between the ischial tuberosities. The female external genitalia, including the urethra and vagina, are within the anterior division, also known as the urogenital triangle, which extends anteriorly to the pubic symphysis. The borders of the posterior triangle, or anal triangle, include the levator ani (superior), perineal membrane (anterior), coccyx (posterior), and the sacrotuberous ligaments (posterolateral). The contents of the anal triangle include the anal canal and the paired ischiorectal fossa. The levator ani and obturator internus muscles as well as the external anal sphincter are within the anal triangle.

The anterior triangle is divided into three layers: subcutaneous, superficial, and deep. The subcutaneous fatty layer contains Camper fascia and is continuous with the posterior triangle, the thigh, and abdominal wall. The superficial layer is an enclosed compartment bound by the perineal membrane, Colles fascia (continuous with Scarpa fascia in the abdominal wall), ischiopubic rami,

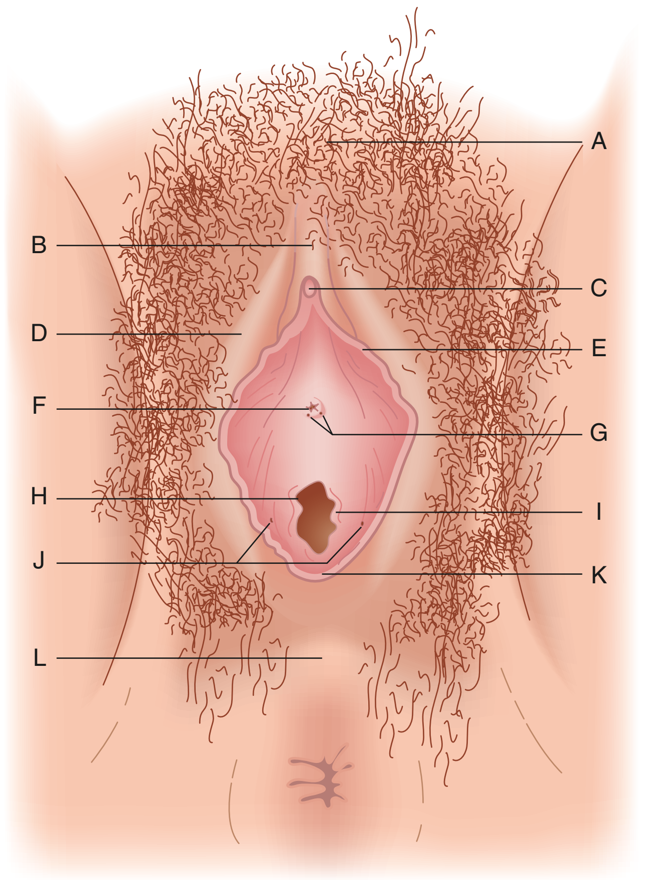

FIGURE 120.1 The eternal genitalia. *A*, Mons pubis; *B*, prepuce; *C*, clitoris; *D*, labia majora; *E*, labia minora; *F*, urethral meatus; *G*, Skene gland ducts; *H*, vagina; *I*, hymenal ring; *J*, Bartholin glands; *K*, posterior fourchette; *L*, perineal body.

and the urethra/vagina. This layer includes many of the important vulvar structures, such as the transverse perineal muscles, bulbocavernosus, and ischiocavernosus overlying the crura of the clitoris, vestibular bulbs, and the neurovascular tissue that supplies the external genitalia. Therefore, clinically, bleeding from a vulvar injury in this space will often be localized and unilateral. The deep layer is mostly a continuation of the fatty tissue in the ischioanal fossa that extends beyond the perineal membrane.

Blood supply to structures within the urogenital triangle is predominantly from a posterior direction from the internal pudendal artery, which, after arising from the internal iliac artery, passes through the pudendal, or Alcock canal, which is a fascial tunnel along the obturator internus muscle below the origin of the levator ani muscle. On emerging from the Alcock canal, the internal pudendal artery sends branches to the urogenital triangle anteriorly. The blood supply to the mons pubis originates anteriorly from the inferior epigastric artery, a branch of the femoral artery. Laterally, the external pudendal artery arises from the femoral artery and supplies the lateral aspect of the vulva. Venous return and lymphatic drainage from the urogenital diaphragm accompany the arterial supply and therefore drain into the internal iliac and femoral veins.

The major nerve supply to the urogenital triangle comes from the internal pudendal nerve, which originates from the S2–S4 anterior rami of the sacral plexus and travels through Alcock canal along with the internal pudendal artery and vein. Anterior branches supply the external genitalia. The mons pubis and anterior labia are supplied by the ilioinguinal and genitofemoral nerves from the lumbar plexus that travel through the inguinal canal and exit through the superficial inguinal ring. All these paired nerves routinely cross the midline for partial innervation of the contralateral side. The dorsal nerve responsible for clitoral erection and sensation is derived from the pelvic splanchnic nerves and reaches the clitoris through the urogenital diaphragm. It is critical to be cognizant of the vascular and neurologic variability as the dorsal nerve of the clitoris has extensive, distinct superficial and deep branching patterns that are at risk of injury during dissection.[2]

Internal Female Reproductive Anatomy (Vagina, Cervix, Uterus, Fallopian Tubes, Ovaries)

Beginning most distal and moving proximal, the internal reproductive anatomic structures include all midline structures (the vagina, cervix, and uterus) and the lateral structures (the fallopian tubes and ovaries; Fig. 120.2). The lower portion of the vagina develops from the endoderm of the urogenital sinus (along with the urethra and vulvar structures). Abnormalities of development in this area can lead to transverse or horizontal septae of the vagina, which may become symptomatic during pubertal development and the onset of menses. The upper portion of the vagina develops in tandem with the cervix, uterus, and fallopian tubes from the Müllerian ducts. Failure of fusion of these ducts as they migrate medially or failure of development completely can lead to a variety of uterine, cervix, and tubal malformations.

Vagina

The vagina is a flexible, expandable fibromuscular tube, which, at rest, is flattened and lies in a mostly horizontal plane if the female is in an upright posture. When examining the full thickness of the vaginal wall, the layers from the center to periphery include the mucosa (stratified squamous epithelium), the lamina propria (collagen, elastic tissue, and the vascular and lymph supply), a muscular layer, and areolar connective tissue, which also contains a rich blood supply. The blood supply to the vagina comes mainly from the vaginal artery, a branch of the internal iliac artery. There are multiple anastomoses with other arteries, including the uterine, internal pudendal, inferior vesical, and middle hemorrhoidal arteries. The nerve supply to the vagina originates from the autonomic nervous system in the lumbosacral plexus (S2–S4), culminating in the pudendal nerve. The majority of sensory innervation lies in the distal portion of the vagina, with very little nerve density in the upper part of the vagina.

Cervix

The cervix is the narrow, distal part of the uterus that can be visualized and palpated at the upper end of the vaginal canal. It is a round, often donut-like structure composed of mostly fibrous tissue and can vary in size. The length of the cervix also varies but averages around 3 cm. It has a central canal, referred to as the *os,* which allows passage into or egress from the uterine cavity. The cells on the vaginal portion of the cervix (ectocervix) transition from squamous epithelium distally to columnar epithelium proximally as you travel up into the cervical canal (endocervix). This change is referred to as the transition zone and is where cervical intraepithelial neoplasia (CIN) occurs. The columnar epithelium produces mucus, which varies in texture depending on hormone influence, and facilitates sperm transport.

FIGURE 120.2 The internal genitalia. The blood supply of the cervix arises from a descending branch of uterine artery and lies laterally at the 3 o'clock and 9 o'clock positions on the cervix. Additionally, the azygos arteries lie in the middle portion of the cervix anteriorly and posteriorly along its axis. There are multiple anastomoses between the azygos arteries and the hemorrhoidal arteries. The cervix is innervated by the parasympathetic system, arising from lumbosacral plexus (S2–S4) with the majority of nerve endings concentrated in the endocervical region.

Uterus

The uterus is an intraperitoneal muscular organ that sits posterior to the bladder and anterior to the rectum. It is held in place by several ligamentous structures. The broad ligaments extend laterally off the uterine corpus and become continuous with the pelvic peritoneum. The round ligaments originate at the uterine cornua and travel laterally through the broad ligament and exit through the inguinal ring, terminating in the labia majora. The cardinal ligaments, which attach laterally to the pelvic diaphragm and fuse medially with the vagina, support the uterus at the level of the cervix. The uterine arteries travel within the cardinal ligament and then superiorly along the lateral aspect of the uterine body, also called the *fundus.* The uterosacral ligaments originate at the upper posterior cervix and attach to the third sacral vertebra, forming an arch that frames the rectum.

The nonpregnant uterus typically weighs between 40 and 80 g. It is often smaller in prepubertal and postmenopausal years compared with the reproductive years. The uterus has three cell layers, similar to other viscous peritoneal organs. The outer layer, called the *serosa,* is very thin and is contiguous with the broad ligaments and pelvic peritoneum. The middle layer of myometrium is composed of smooth muscle, which lies in three distinct layers. The uterine cavity is lined with endometrium, a mucous epithelial layer that varies in thickness depending on hormonal influences.

The blood supply to the uterus includes both uterine arteries, which branch off the internal iliac arteries, and the ovarian arteries, which come directly off the abdominal aorta and travel adjacent to the ovary toward the uterus. The uterus has both sympathetic and parasympathetic innervation. The sympathetic innervation travels via the hypogastric and ovarian plexus. The parasympathetic innervation comes from the lumbosacral plexus (S2–S4). Afferent fibers from the uterus returning to the spinal cord travel with the sympathetic innervation within the lumbosacral plexus (T11–T12).

Fallopian Tubes

The fallopian tubes, also referred to as the *oviducts,* originate at the upper lateral aspect of the uterus (called the *cornua*) and extend laterally approximately 10 to 14 cm in length, coiling around the ipsilateral ovary distally. The fallopian tube has four distinct anatomic sections. The interstitial part traverses the uterine wall, is completely bordered by myometrium, and is only 1 to 2 cm in length. The narrow isthmus portion begins as the tube leaves the uterus, measures around 4 cm in length, and contains the most muscular region of the tube. The ampullary region is wider, averages 4 to 6 cm in length, and is where fertilization typically occurs. The final segment is the infundibulum, which is mostly composed of fimbriae, which are finger-like projections that extend out from the tube, surround the ostia, and cause this portion of the tube to be funnel shaped.

Like the uterus, the fallopian tubes are composed of several layers. The mucosa of the tube is made up of different types of epithelial cells: columnar ciliated, secretory, and narrow peg. The ratio of these cell types depends on the anatomic region of the tube. Under the mucosa is the lamina propria, followed by the muscular layer, and finally the adventitial layer, which is adjacent to the peritoneal cavity.

The blood supply to the fallopian tube travels through the mesosalpinx and originates from branches of the ovarian and uterine arteries. The tubes receive innervation from both the sympathetic and parasympathetic nervous systems via the uterine and ovarian plexuses.

Ovaries

The ovaries are paired, oval-shaped organs lateral in location and white, usually around 2 to 3 cm in largest diameter. They are located just inferior to the pelvic brim at the infundibulum end of the fallopian tubes. The ovaries develop from the gonadal ridge, which sits adjacent to the mesonephric duct; thus, the urinary system and reproductive system develop in close association. The ovaries are connected to the uterus via the uteroovarian ligament, which contains an anastomotic blood supply between these two structures. Additionally, the ovaries are held in place by the posterior leaf of the broad ligament and the infundibulopelvic ligament, which travels down the lateral sidewall and contains the major ovarian blood supply.

The ovary has three distinct sections: the outer cortex, the central medulla, and the hilum, which is where the mesovarium (the structure that anastomoses the infundibulopelvic ligament and the periuterine blood supply via the broad ligament) attaches to the ovary. The ovaries contain several cell types including the oocytes, which number 1 to 2 million at birth. The oocytes mature inside small, fluid-filled cysts called *follicles,* which sit just under the surface epithelium composed of cuboidal epithelium. The central medulla is mostly made up of stroma and blood vessels.

The blood supply to the ovary comes from the ovarian artery, a branch off the abdominal aorta that travels along the lateral abdomen and pelvis in the infundibulopelvic ligament. Additionally, within the mesovarium there are many anastomoses between the ovarian artery and the uterine artery. The innervation of the ovary also travels via the infundibulopelvic ligament and includes autonomic and sensory nerve fibers from the ovarian, hypogastric, and aortic plexuses.

Other Relevant Female Pelvic Anatomy

Anatomic Spaces

The female pelvis contains several key potential avascular spaces, an understanding of which is required by any surgeon operating in this area (Fig. 120.3). The two lateral retroperitoneal spaces include the paravesical and pararectal spaces. The paravesical space is bordered by the external iliac artery laterally, the bladder medially, the pubic symphysis anteriorly, and the cardinal ligament posteriorly. Key anterior to posterior spaces include the retropubic, vesicovaginal, rectovaginal, and retrorectal/presacral spaces. Developing these avascular spaces facilitates identification of critical pelvic structures, particularly when normal anatomy is altered from both benign and malignant conditions. A keen understanding of these spaces is necessary to safely operate in the pelvis and to mitigate neurovascular, urinary, and gastrointestinal injuries.

Vascular Structures

A keen understanding of vascular anatomy and the accompanying pelvic landmarks is essential when performing gynecologic procedures (Fig. 120.4). The common iliac vessels bifurcate at the level of the sacral promontory/pelvic brim into the external iliac and internal iliac vessels, which course along the pelvic sidewalls. The external iliac vessels course under the inguinal ligament to become the femoral artery and vein. The internal iliac artery bifurcates into an anterior and posterior division. The female pelvic structures derive much of their arterial vascular supply from vessels that branch from the anterior division. Ligation of the anterior division distal to where the posterior division branches is a technique often used in the setting of excessive pelvic hemorrhage. Key branches of the anterior division include the uterine and vaginal arteries; the inferior, middle, and superior vesical arteries; and the middle rectal artery. Other key branches off the anterior division include the obturator, inferior gluteal, and pudendal arteries. The ovarian arteries, which originate from the aorta, provide another major vascular source to the pelvic structures, namely the ovaries and uterus. The right

and left ovarian veins drain into the inferior vena cava and the left renal vein, respectively.

Neurologic Structures

The lumbosacral nerve plexus, which originates from nerve roots from the twelfth thoracic vertebral body to the fourth sacral vertebral body (T12–S4), provides the major nerve structures in the pelvis (Fig. 120.5). The primary motor nerves emanating from the lumbosacral nerve plexus include the femoral, sciatic, and obturator nerves. The primary sensory nerves include the iliohypogastric, ilioinguinal, genitofemoral, lateral femoral cutaneous, femoral, sciatic, and pudendal nerves. A description of these nerves, their origin, their motor and sensory functions, and symptoms when injured is included in Table 120.1.

Nerve injuries occur in 1% to 2% of gynecologic cases.[3] The most common nerves injured during gynecologic surgery include the femoral, ilioinguinal, pudendal, obturator, lateral cutaneous, iliohypogastric, and genitofemoral nerves. These nerves can be injured as a result of malpositioning the patient in the lithotomy position, incorrect placement of self-retaining retractors, nerve transection, direct nerve entrapment, or hematoma formation. Safe positioning of the patient to maximize exposure and minimize injury is essential in gynecologic surgery.

Urinary Tract Structures

The ureters and bladder are key pelvic structures that require strict attention during the course of most gynecologic procedures. The ureters course retroperitoneally down the lateral pelvic walls, and at the level of the sacral promontory, cross over the common iliac arteries at the pelvic brim (see Figs. 120.2 and 120.4). At the pelvic brim, the ureters are close to the ovaries, and care must be taken to properly identify and avoid them during ligation of the ovarian vessels. The ureters continue along the medial aspects of the pelvic peritoneum under the uterine arteries and then traverse into the bladder laterally in an oblique fashion. The ureters are also at risk for damage during clamping, incision, and ligation of the uterine vessels, the cardinal and uterosacral ligaments, and with suturing of the vaginal cuff after hysterectomy. Dissecting the ureters off their attachments to the peritoneum, with or without isolating them with vessel loops, is a technique to reduce the risk of ureteral injury.

The bladder is intimately involved with the anterior uterus, cervix, and vagina. The bladder must be carefully dissected off these structures during a hysterectomy. This often involves incision of the vesicouterine peritoneum and identifying the vesicovaginal space between the bladder and vagina. Dissection of the bladder can be made more difficult by scarring from prior cesarean section, endometriosis, or cancer.

Injuries to the ureters and bladder are overall reported to occur in less than 1% of patients undergoing major gynecologic surgery, including hysterectomy.[4,5] Cystoscopy is often used to confirm an intact bladder and bilateral ureteral efflux after gynecologic procedures that carry a high risk of urologic injury. Cystoscopy after laparoscopic hysterectomy has been shown to be cost-effective when the lower urinary tract injury rate is estimated to be 1% to 2%; thus, a selective approach is advocated when determining need for cystoscopy.[6] Thermal injuries remain difficult to identify during the intraoperative session even when using cystoscopy due to their delayed presentation.

TABLE 120.1 Lumbosacral Nerve Plexus

NERVE	ORIGIN	MOTOR FUNCTION	SENSORY FUNCTION	INJURY SYMPTOMS
Ilioinguinal	T12–L1	None	Groin, symphysis	Sharp, burning pain radiating from incision site to groin or symphysis
Iliohypogastric	T12–L1	None	Mons, lateral labia, upper inner thigh	Sharp, burning pain radiating from incision site to mons, labia, or thigh
Genitofemoral	L1–L2	None	Upper labia, anterior superior thigh	Pain or paresthesia labia and femoral triangle
Lateral femoral	L2–L3	None	Anterior and posterior lateral thigh	Pain or paresthesia anterior and posterolateral thigh
Pudendal	S2–S4	None	Perineum	Perineal pain
Cutaneous femoral	L2–L4	Hip flexion, adduction Knee extension	Anterior and medial thigh, medial calf	Unable to climb stairs
Obturator	L2–L4	Thigh adduction	None	Minor ambulatory problems
Sciatic	L4–S3	Hip extension, knee flexion	None	Foot drop
Common peroneal		Foot dorsiflexion	Lateral calf	Cavus deformity foot
Tibial		Foot eversion	Dorsum of foot	
		Foot plantar flexion	Toes	
		Foot inversion	Plantar foot surface	

Intestinal Tract Structures

The distal ileum, cecum, and appendix as well as the sigmoid colon and rectum are key gastrointestinal structures located near or within the pelvis. Gastrointestinal adhesions can occur as a result of surgeries, and careful attention is required to lyse adhesions in this setting to restore normal pelvic anatomy before completing any gynecologic procedure. These intestinal structures can also be involved as the result of various gynecologic pathology such as tuboovarian abscesses, endometriosis, and ovarian neoplasms. It is important to carefully inspect the intestinal organs to ensure there has been no occult injury, which is reported to occur in less than 1% of patients undergoing hysterectomy.[7] A "bubble" test, which involves insufflating the rectum with air with compression of the sigmoid and filling the pelvis with saline or water, can be used to detect an occult sigmoid injury.

COMMON VULVA AND VAGINAL SURGICAL DISEASES AND PROCEDURES

Common vulva and vaginal surgical diseases and procedures are listed in Table 120.2. A description of these diseases and management options follows.

TABLE 120.2 Common Vulvar and Vaginal Surgical Diseases and Procedures

DISEASE	PROCEDURE OPTIONS
Bartholin cyst/abscess	Incision and drainage Marsupialization Excision
Vulvar intraepithelial neoplasia	Wide local excision Laser
Vulvar cancer	Radical vulvectomy with sentinel node biopsy or inguinal femoral lymphadenectomy
Vaginal intraepithelial neoplasia	Partial vaginectomy Laser
Vaginal cancer	Radical hysterectomy (rarely)
Prolapse	Sacrocolpopexy Sacrospinous ligament suspension Uterosacral ligament suspension Anterior colporrhaphy Posterior colporrhaphy Colpocleisis

Common Vulvar and Vaginal Surgical Diseases

Vulvar Infection/Abscess

Vulvar infections can range from superficial cellulitis to severe necrotizing fasciitis. Rapid diagnosis and initiation of treatment with broad-spectrum antibiotics and debridement, when appropriate, are essential. Risk factors for vulvar infection include diabetes, obesity, immunosuppression, pregnancy, and trauma.[8] In general, a vulvar abscess larger than 2 cm will necessitate surgical intervention with at least incision and drainage for adequate treatment.

Blockage of the Bartholin glands can result in accumulation of mucus and may lead to obstruction and abscess formation, presenting as a unilateral painful vulvar mass. Patients with a symptomatic Bartholin gland cyst or abscess often require surgical intervention with incision and drainage and placement of a Word catheter or with marsupialization. Marsupialization is indicated for recurrent infections or when the size of abscess precludes incision and drainage. Biopsy is indicated for solid components and suspicion of malignancy. In rare instances, excision of the gland is indicated for recurrent infections and for malignancy.

Vulvar Crohn disease is a granulomatous inflammatory process that can lead to abscess and fistula formation from the anus to the vulva or perineum.[9] Presenting symptoms include erythema, edema, and "knife-cut ulcerations" of the external genitalia. Up to 30% of patients will initially be diagnosed with Crohn disease due to the vulvar manifestations. Treatment centers on managing the primary disease process with immune suppression while balancing the risk of worsening infection. Surgery is often a treatment of last resort due to the high recurrence rate and poor healing outcomes. Debridement or drainage of abscess locally is performed more commonly than fistula excision.

Hidradenitis suppurativa is a chronic inflammation of the apocrine-glandular tissue and is commonly seen at the vulvar and inguinal folds. Subsurface nodules can coalesce and form abscesses under the skin surface with resultant sinus tracts and scarring at the skin, creating disfigurement and pain. When medical therapies are exhausted, surgery can be considered. Deroofing of fistula tracts or incision of abscess may provide immediate short-term relief. Wide excision has shown the lowest risk of recurrence compared with local excisions, but often local approaches will require less recovery time.[10] Postoperative wound care and pain management are important. Negative pressure wound therapy with delayed reconstruction and grafting may be useful. The use of perioperative medical therapy, including biologics is recommended.

Necrotizing fasciitis is a medical and surgical emergency that requires multidisciplinary care. Patients at increased risk of necrotizing fasciitis include diabetics, tobacco users, and postoperative/pregnancy state. Signs such as progressive edema, fever, pain out of proportion to findings, and expanding skin induration should prompt high suspicion for necrotizing fasciitis. Skin changes often occur late in the disease process. Treatment should not be delayed to obtain imaging and includes broad-spectrum antibiotics as well as surgical debridement of necrotic tissue along with supportive critical care from a multidisciplinary team.

Vulva Intraepithelial Neoplasia

Vulva intraepithelial neoplasia (VIN) is a premalignant condition of the vulva. In 2015, the International Society for the Study for Vulvovaginal Disease (ISSVD) recommended using a two-tier grading system for classical VIN, which includes low-grade squamous intraepithelial lesion (LSIL), high-grade squamous intraepithelial lesion (HSIL), and a third category that separates VIN differentiated type.[11] The majority of LSIL and HSIL VIN is associated with the human papillomavirus (HPV), tends to occur in younger patients, and is multifocal. The pathogenesis of VIN differentiated type is less well understood but tends to be associated with vulvar dermatoses such as lichen sclerosis, seen more commonly in older patients, and is not associated with HPV. Differentiated VIN is associated with a high 10-year risk for progression to vulvar cancer highlighting the need for timely diagnosis, which is made more challenging given the subtle signs and symptoms.[11] Common symptoms of VIN are vulvar itching and pain, although up to 40% of VIN does not have symptoms. Management includes colposcopy and biopsy to confirm the diagnosis. LSIL may be observed or treated with topical therapy such as imiquimod. The mainstay of treatment for HSIL is either wide local excision or laser ablation. Recurrence rates after treatment are high; therefore, continued monitoring after therapy is required.

Vulvar Cancer

Carcinoma of the vulva is a rare gynecologic cancer but still significantly contributes to overall mortality from reproductive tract cancers.[12] Squamous cell carcinoma is the most common histology. Less common histologic subtypes include verrucous, basal cell, melanoma, sarcoma, extramammary Paget, and Bartholin gland carcinoma. Risk factors for vulva cancer include smoking, HPV infection, VIN, cervical dysplasia or cancer, lichen sclerosis, and immunodeficiency. The most common presentation is a symptomatic nodular or ulcerative vulva lesion. Treatment is based upon clinical stage. For stage IA cancers that are confined to the vulva and less than 1 mm of invasion, with clinically negative lymph nodes, simple vulvectomy is reasonable. Surgical resection involves radical vulvectomy with bilateral inguinal femoral lymph node dissection through separate incisions, which decreases morbidity. Sentinel lymph node (SLN) mapping is a reasonable alternative to full inguinofemoral lymph node dissection with less morbidity in select patients with small tumors. Treatment with chemoradiation has been the preferred strategy for locally advanced unresectable disease that involves the urethral meatus, vagina, or anus.

Vaginal Intraepithelial Neoplasia

Vaginal intraepithelial neoplasia (VaIN) is a premalignant condition of the vagina. Like VIN, it is classified using a two-tier grading system LSIL (previously VaIN 1) and HSIL (previously VaIN II/III). Patients are often asymptomatic. Risk factors are similar to that for patients with VIN. Management is also like that for patients with VIN, albeit laser ablation is more frequently considered over partial vaginectomy for HSIL VaIN lesions. In patients posthysterectomy, excision may be preferred. Recurrence is not uncommon and close follow-up is recommended.[13]

Vaginal Cancer

Vaginal cancer is also quite rare. Squamous cell carcinoma is the most common histology. Less common histologic subtypes include adenocarcinoma, sarcoma, and melanoma. Risk factors other than those mentioned previously for vulva cancer include diethylstilbestrol exposure in utero and prior radiation. The most common presenting symptom is vaginal bleeding followed by vaginal discharge, change in urinary symptoms, or pain. Stage is the most significant prognostic feature. Most patients with vaginal cancer are treated with the combination of radiation and chemotherapy. Radical hysterectomy with upper vaginectomy is an option for the rare select patient with a small stage I cancer confined to the vaginal mucosa and located in the posterior vaginal fornix.

Pelvic Organ Prolapse

Pelvic organ prolapse is the herniation or downward displacement of the bladder (anterior vagina), cervix or vaginal cuff (apex), or rectum (posterior vagina) beyond their normal position. Risk factors include parity, age, obesity, chronic constipation, chronic obstructive pulmonary disease, connective tissue disorders, and smoking. The symptom most predictive for prolapse is the presence of a vaginal bulge. Other symptoms include pelvic pressure/heaviness and/or changes in bowel or bladder function. Treatment options include nonsurgical interventions, including pessary and pelvic floor physical therapy, as well as surgical intervention. Both conservative management and surgical options should be outlined as treatment options.

Pelvic reconstructive surgery for pelvic organ prolapse is individualized with the goal to restore normal anatomy and function of the anterior, posterior, and apical vaginal compartments. The apical defect, when present, is recognized as the key anatomic area to address in prolapse repair, which can be approached either abdominally or transvaginally. The most common procedures for repair of apical prolapse are abdominal sacrocolpopexy (or its minimally invasive laparoscopic or robotic variants), transvaginal sacrospinous ligament suspension, and transvaginal or laparoscopic uterosacral ligament suspension.[14–16] Repair of apical prolapse abdominally with sacrocolpopexy results in a lower rate of recurrence when compared with transvaginal approaches; however, it is associated with longer surgical time and delay in return to normal activities.

Patients with pelvic organ prolapse often have several compartments that are prolapsed and benefit from repair that addresses each of the affected compartments. Anterior and posterior colporrhaphy are often not needed when an abdominal sacrocolpopexy is performed as repair of apical defect often corrects the anterior and posterior defects.[17] However, anterior and posterior colporrhaphy are more often performed when the reconstruction is performed transvaginally in conjunction with uterosacral or sacrospinous ligament suspension.

Rates of recurrence have varied substantially in different studies, and a standard of "success" remains under discussion. Recent data suggest that recurrence rates are approximately 15%; however, the definition of "surgical success" in research studies has broadened over time to consider both objective findings, such as stage on examination, and subjective patient-reported symptoms.[18] Outcomes at 5 years are similar between uterosacral ligament suspension and sacrospinous ligament suspension with reported failure rates of 62% and 70%, respectively, although prolapse symptom scores remain improved despite the anatomic findings of prolapse.[19,20] Recurrence of prolapse after native tissue repairs is approximately 16% at 12 months after repair with younger age identified as a risk factor.[16]

Although most cases of pelvic organ prolapse are treated with reconstructive vaginal surgery as noted previously, there are some instances in which vaginal reconstruction may not be desired or an option. For patients who are not candidates for surgical reconstruction, and who are no longer sexually active, obliteration of the vaginal canal can alleviate the symptoms of pelvic organ prolapse without high surgical morbidity. Additional benefits of colpocleisis are shorter operative time, low risk of recurrence, and similar patient satisfaction making this an appropriate choice for older patients with multiple medical comorbidities who are not sexually active.

Common Vulva and Vaginal Surgical Procedures

Treatment of Vulvar Infection

Incision and drainage of a vulvar cyst or abscess of any etiology is performed by stabilizing the cyst or abscess and making an incision over the center of the cyst or abscess on the medial aspect of the lesion just outside the hymenal ring (Fig. 120.6). A common

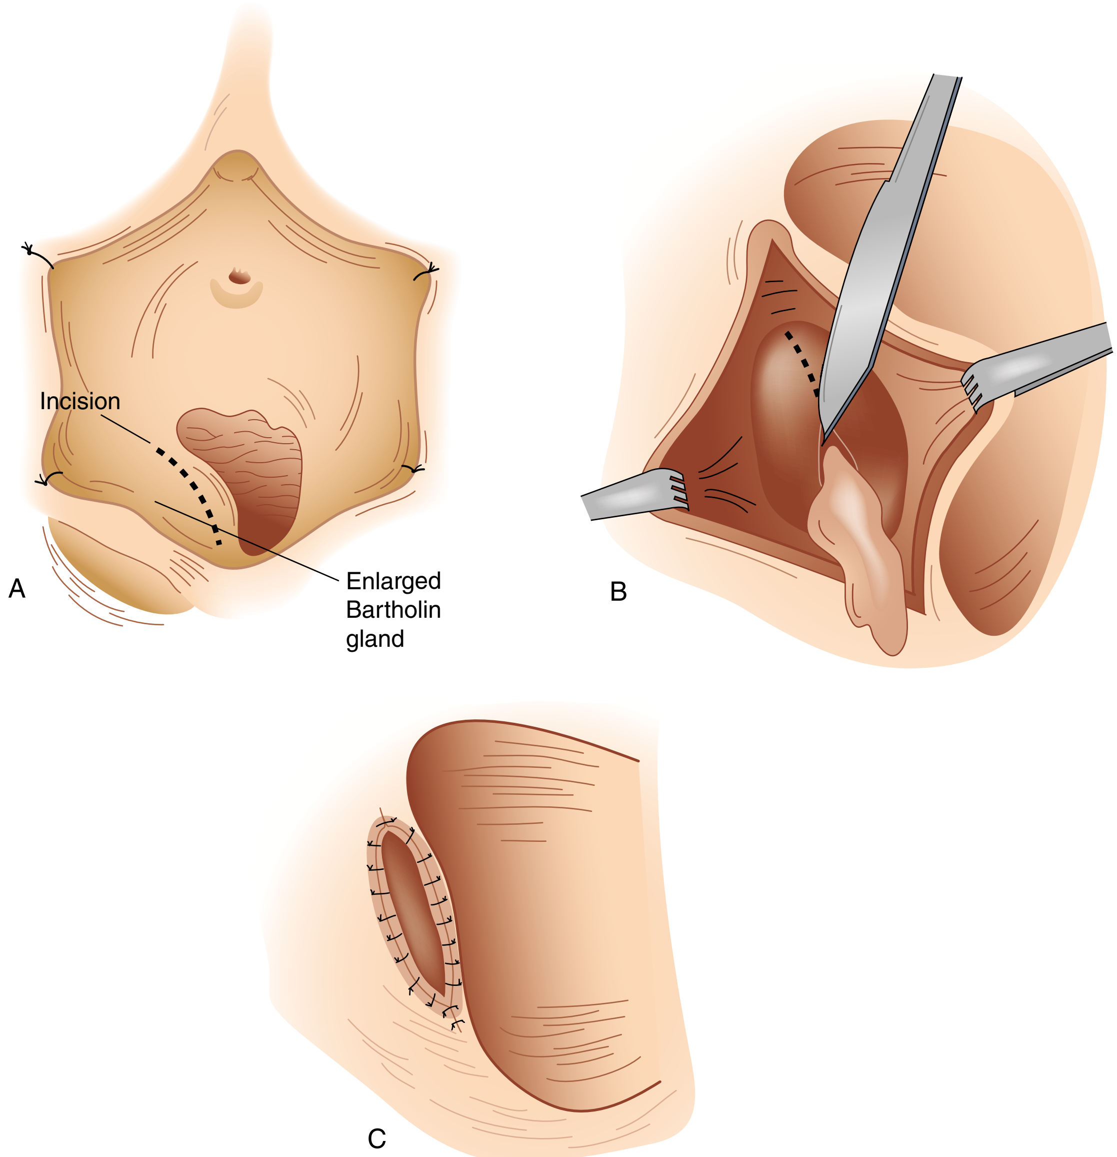

FIGURE 120.6 Bartholin gland marsupialization. (A) Retraction of the labia and incision over the mucosa of the vagina. (B) Wall of the gland is excised. (C) Completed marsupialization. (Adapted from Mitchell CW, Wheeless CR. *Atlas of Pelvic Surgery*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1997.)

mistake is to make the incision on the lateral aspect of the vulva. Care should be taken when breaking up loculations blindly as this manipulation may be close to rectal tissue already impacted by the inflammatory changes of infection. Specifically for a Bartholin gland abscess, a small Word catheter is placed into the cyst for drainage and reevaluated on a weekly basis. Bartholin gland abscesses are often polymicrobial. Culture of purulent fluid can be obtained to evaluate for methicillin-resistant *Staphylococcus aureus* and treated empirically. Marsupialization of a Bartholin gland cyst is performed by creating an elliptical incision in the vestibular mucosa down to the wall of the gland. The wall of the gland is incised along the entire length of the ellipse. The contents are evacuated, and the wall of the cyst is sutured to the vestibular mucosa using 3-0 synthetic absorbable sutures in an interrupted fashion or using a baseball stitch.

Surgical management of hidradenitis suppurativa includes deroofing of sinus fistula tracts and wide en bloc excisions.[10] Both of these procedures are ideally performed by a surgeon with expertise in the dissection and tracking of the sinuses to optimize removal and minimize recurrence. When deroofing a tract, the skin over it is incised, and the edges are beveled leaving an open wound that heals secondarily. Deroofing is preferred over simple incision and drainage as it has a lower rate of recurrence. Wide excision, although more invasive, provides a higher likelihood of a disease-free state. Surgical planning should include consideration of superficial subcutaneous removal versus a deeper dissection. Split-thickness skin grafts may be necessary unless healing by secondary intention is possible.

Necrotizing fasciitis requires prompt surgical attention with debridement and tissue excision.[8,21] Multiple disciplines may be involved in a complex case, including gynecology, general surgery, plastics, and/or trauma. The surgical approach should include removal of all necrotic tissue until healthy tissue is revealed, typically noted by bleeding and resistance within the tissue. Wound care with negative pressure wound therapy or hyperbaric oxygen therapy may be useful adjuncts to healing.

Wide Local Excision/Laser of the Vulva

A wide local excision is a superficial excision of a vulva lesion and is used in the treatment of HSIL VIN (Fig. 120.7). The lesion is outlined with 1-cm margins. If the lesion is close to vital structures such as the anus, clitoris, or urethra, smaller margins may be used for cosmesis or to preserve function. After making an incision along the outline, the apex of the skin is then elevated, and the epidermis is removed to a depth of 2 to 3 mm. Removal of dermis is not necessary for preinvasive disease. The defect is reapproximated using running or interrupted sutures depending on surgeon preference and size of lesion.

CO_2 laser vaporization is commonly used to treat LSIL VIN and may be an alternative to surgical resection for HSIL VIN.[22] For HSIL VIN, CO_2 laser vaporization is best used for patients with multifocal disease; with disease close to vital structures such as the anus, urethra, or clitoris; or with extensive VIN lesions in which surgical resection would be disfiguring. CO_2 laser vaporization should be used only when there is a low clinical suspicion for malignancy and after vulvar biopsies have confirmed no evidence of invasive cancer. A depth of 1 mm is used on nonhair-bearing areas of the vulva and 3 mm on hair-bearing areas of the vulva. Colposcopy is used to increase precision with laser therapy.

Laser of the Vagina/Partial Vaginectomy

For HSIL VaIN, CO_2 laser vaporization is a useful preferred approach for newly diagnosed patients and has less risk of injury to adjacent structures. Ablation of the involved superficial vaginal dermis along with a 1- to 2-cm margin should suffice. A partial vaginectomy involves excision of the vaginal epithelium and is most used for patients with HSIL VaIN who have had a hysterectomy and recurred after CO_2 laser procedure due to cells buried within the scar that laser cannot adequately treat. The surgical approach is usually vaginally, and the lesion with a 1- to 2-cm margin is excised. Care is taken to avoid injury to the bladder or colon. Depending on the size of the lesion, vaginal reconstruction may be required.

Radical Vulvectomy With Sentinel Node Mapping and Biopsy or Inguinal Femoral Lymphadenectomy

Radical vulvectomy for vulva cancer can be either total or partial depending on the extent of involvement and lesion location.[12] The procedure starts by outlining the vulva cancer lesion with a 2-cm margin. As with a wide local incision, smaller margins are reasonable to preserve function around vital structures. In contrast to a wide local excision where just the superficial vulva skin

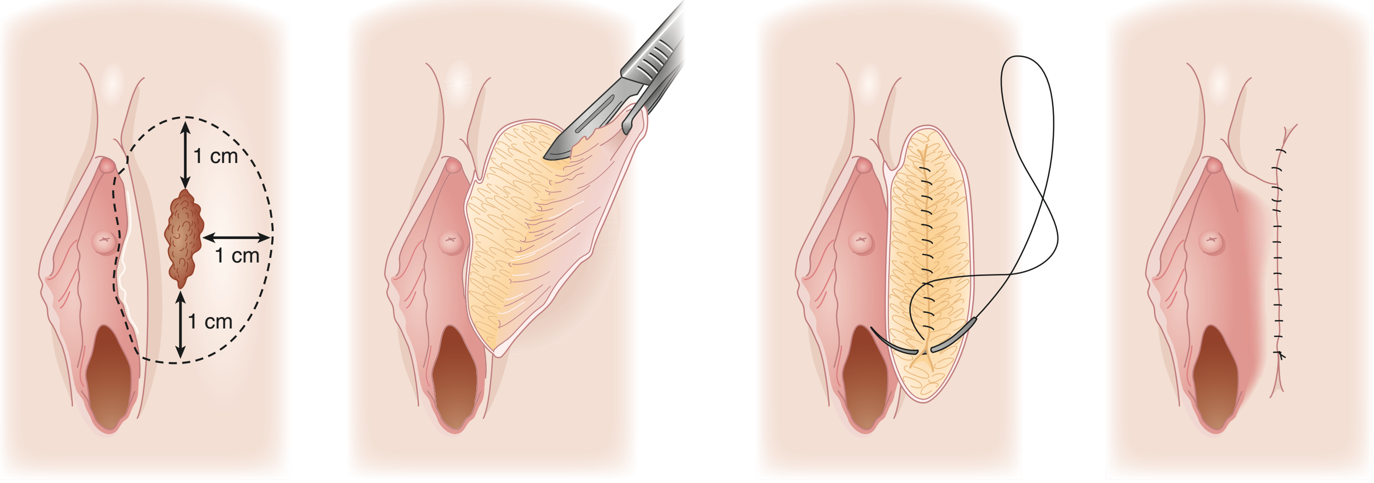

FIGURE 120.7 Wide local excision of vaginal intraepithelial neoplasia lesion.

is removed, the incision in a radical vulvectomy is carried down beneath the subcutaneous tissue to the fascia of the urogenital diaphragm. Care is taken to identify and ligate the clitoris and its vessels anteriorly and the bulbocavernosus muscles and the internal pudendal vessels laterally, as applicable. The specimen is amputated and marked for orientation. Primary closure is achieved by closing the subcutaneous tissue with interrupted absorbable suture. Skin closure may be performed using running or interrupted sutures.

SLN mapping and biopsy is the preferred technique for lymph node evaluation in early stage unifocal vulvar cancer with lesions that are less than 4 cm in diameter, clinically negative lymph nodes, and no inguinofemoral surgeries.[12] The vulvar lesion is injected preoperatively with a radioactive isotype subdermally at four sites around it. A preoperative nuclear scan or single photon emission computed tomography (SPECT) may be used for identifying the sentinel node and for surgical planning.

If no SLN is identified or a patient is not a candidate for SLN dissection, a full inguinofemoral lymphadenectomy is performed. An incision is made parallel to and approximately 2 cm below the inguinal ligament. All lymph node–bearing tissue between the inguinal ligament superiorly, the sartorius muscle laterally, and the adductor longus muscle medially is removed. Preservation of the great saphenous decreases rates of lymphedema. The cribriform fascia may be opened to remove the deep femoral lymph nodes. A suction drain is placed, and primary closure is achieved by closing the subcutaneous tissue with interrupted absorbable suture. Skin closure is performed using a running absorbable suture or staples.

Pelvic Prolapse Procedures

Vault suspensions (abdominal sacrocolpopexy, sacrospinous ligament suspension, uterosacral ligament suspension). Abdominal sacrocolpopexy may be performed via laparotomy, laparoscopy, or robotic approaches and either concurrently with hysterectomy or in patients with posthysterectomy apical prolapse. The vesicovaginal space is developed and the bladder dissected off the anterior vagina while the rectovaginal space is developed, and the rectum dissected off the posterior vagina. A Y-shaped polypropylene mesh graph is sutured to the anterior and posterior vagina as well as the cervix if present. The peritoneum over the sacral promontory is then incised. Permanent suture is used to secure the graft to the anterior longitudinal ligament at the anterior sacrum. Care is taken to avoid injuring the middle sacral vessels. The retroperitoneum is then reapproximated.

Sacrospinous ligament suspension is the most studied transvaginal procedure for treating apical prolapse. After opening the rectovaginal space, the pararectal space is entered by dissecting the rectum from the lateral vagina to the level of the ischial spine. One to two sutures are placed through the sacrospinous ligament with care taken to protect the pudendal vessels and nerves and then through the muscularis of the posterior vaginal epithelium, and later ligated with a pulley stitch.

A high uterosacral ligament suspension is typically performed after completion of a total vaginal hysterectomy. After hysterectomy, the bowels are packed away, and the uterosacral ligaments are identified. Delayed absorbable sutures (one to three) are passed through the uterosacral ligament bilaterally. The first suture is passed just above the level of the ischial spine and second suture is more proximal. Cystoscopy is then performed to ensure integrity of the bladder and efflux of urine from both ureteral orifices. The sutures are then passed through the cervicovaginal (anterior) fascia and epithelium then through the posterior rectovaginal fascia and vaginal epithelium at the vaginal apex to suspend the vagina anteriorly, posteriorly, and apically.

Anterior/posterior colporrhaphy. Anterior colporrhaphy begins with a full-thickness incision of the anterior vaginal epithelium and entry to the vesicovaginal space, and the incision is extended to the level of the apex of the cystocele. Dissection continues laterally toward the pubic rami. The pubocervical fascia is plicated in the midline using a series of interrupted sutures of delayed absorbable suture from the bladder neck to the bladder base. Excess vaginal skin, when present, should be excised. The anterior vaginal epithelium is closed with a delayed absorbable suture.

Posterior colporrhaphy is performed by incising the posterior vaginal epithelium vertically past the rectocele, entry to the rectovaginal space, and the incision is extended for the full length of the rectocele. The Denonvilliers' fascia is identified, and the rectocele is dissected off the vagina laterally to the level of the levator ani muscles. The rectovaginal septum is plicated to the midline with delayed absorbable suture. If there is excess vaginal epithelium, this is often excised and then closed with a running suture of delayed absorbable suture. Distal rectoceles are often associated with a perineal defect. The perineal muscles including the transverse perineal and bulbocavernosus muscles are reapproximated. Digital rectal examination should be performed at completion to ensure that a rectal injury did not occur. Care must be taken to avoid over narrowing the vagina or introitus.

Colpocleisis. The most commonly performed colpocleisis technique is the LeFort (partial) procedure, which involves obliteration of the vaginal canal when the uterus is left in situ. This procedure should be avoided in patients with high risk of uterine or cervix cancer as future sampling cannot be performed. Appropriate preoperative workup should include transvaginal ultrasound or endometrial biopsy and Pap smear. For the LeFort procedure, traction is placed on cervix and a significant rectangular-shaped portion of the anterior vaginal epithelium is incised and denuded. The bladder neck is plicated with delayed absorbable suture. A similar portion of the posterior vaginal epithelium is then incised and denuded. The uterine and vaginal prolapse are reduced, and the anterior and posterior denuded vaginal walls are reapproximated in a way that leaves bilateral epithelial-lined tunnels to allow for drainage of cervical mucus.

Colpectomy with total colpocleisis is performed in a female who has had a hysterectomy. Procedurally, the vaginal epithelium is excised, and the underlying vaginal connective tissue is reapproximated with serial purse-string absorbable sutures until the prolapse is reduced. Severe urinary incontinence may result from iatrogenically opening the bladder neck if the colpocleisis is brought too close to the bladder neck.

COMMON CERVICAL SURGICAL DISEASES AND PROCEDURES

Common cervical surgical diseases and procedures are listed in Table 120.3. A description of these diseases and management options follow.

Common Cervical Surgical Diseases

Cervical Intraepithelial Neoplasia

CIN is a premalignant condition of the cervix caused by HPV infection. The lifetime cumulative risk of HPV infection is 84% for those with at least one sexual partner; however, the majority of

TABLE 120.3 **Common Cervical Surgical Diseases and Procedures**

DISEASE	PROCEDURE OPTIONS
Cervical intraepithelial neoplasia	Loop electrosurgical excision procedure Cold-knife conization
Cervical cancer	Cold-knife conization/simple hysterectomy (microinvasive disease) Radical hysterectomy/trachelectomy with sentinel node biopsy or pelvic lymphadenectomy ± paraaortic lymphadenectomy

HPV infections are transient and do not lead to the development of CIN.[23] Persistent high-risk HPV (hrHPV) infection is a necessary, but not sufficient, cause of cervical cancer. hrHPV types, particularly 16 and 18, have a high rate of progression to CIN and, if not treated, to invasive cancer. The average time from HPV infection to invasive disease is generally over 15 years. Risks factors for HPV infection and CIN include early sexual debut, multiple sexual partners, and a history of sexually transmitted infections, including HIV. Risk factors for persistent HPV infection are not fully understood but include an immunocompromised state and smoking.

HPV vaccines significantly reduce the risk of anogenital warts and CIN. Gardasil 9, which prevents HPV-associated anogenital warts and CIN caused by HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58, was approved in 2018 for males and females ages 9 to 45.[24] Patients previously infected with HPV, including those with a history of cervical excision procedures from high-grade lesions, should still be offered the vaccination in accordance with guidelines.

Over the past seven decades, cervical cancer screening with cytologic evaluation of the cervix (the "Pap" smear) has resulted in significant decreases in the incidence of and mortality associated with cervical cancer primarily in developed countries.[25] Current available screening tools include cytology or primary hrHPV testing alone or cotesting with both methods. In average-risk patients, hrHPV testing is preferred for screening.[26] However, universal access to this testing, particularly in low-resource settings, is not yet available, and given these communities may disproportionately suffer from cervical cancer, cytology remains an acceptable form of screening. The age to initiate screening has varied and current recommendations suggest 21 years of age. Underscreening of young patients, particularly in underserved populations, is problematic and further raising of the age of screening could further amplify inequities in these vulnerable populations.[27]

The American Society for Colposcopy and Cervical Pathology (ASCCP) has developed algorithms to guide healthcare professions on the workup of abnormal cytology or HPV screening with a focus on instituting cervical treatment in patients with increased risk and expanded surveillance periods for those at lower risk.[26] Colposcopic evaluation of the cervix with biopsy of acetowhite lesions with vascular changes (mosaicism, punctuation) suggestive of CIN is recommended for patients who have abnormal cervical cancer screening results. The ASCCP and College of American Pathologists recommend use of a two-tier grading system, LSIL and HSIL, to classify biopsied lesions suggestive of CIN. HSIL lesion treatment is ideally an excisional procedure, such as a loop electrosurgical excision procedure (LEEP) or a cold-knife conization (CKC) over an ablative approach for pathology review and examination of margins. Adenocarcinoma in situ (AIS) should be treated with an excisional procedure.

Early detection and treatment of premalignant conditions is essential to preventing cervical cancer. In resource-constrained, low-income countries, the use of "see and treat" approaches have been implemented in lieu of the traditional screening used in resource-rich and high-income countries.

Cervical Cancer

Cervical cancer in the United States has declined by over 65% due to screening and early detection, but it remains one of the most common cancers worldwide.[25,28] Cervical cancer is the leading cause of morbidity and mortality due to cancer in patients living in low-income countries.[25,29] The impact of HPV vaccination on the incidence of cervical cancer provides an opportunity to nearly eradicate this disease. Low-income and middle-income countries with a higher burden of disease have the potential to greatly benefit even more from widespread initiatives to administer HPV vaccines. Efforts from agencies, such as the World Health Organization (WHO), to vaccinate 90% of all females by age 15, screen at least 70% of patients age 35 to 45 years twice, and provide treatment to at least 90% of HSIL/LSIL are projected to decrease the incidence of cervical cancer to less than 4 per 100,000.[29]

In high-income countries, cervical cancer affects a disproportionate percentage of patients of low socioeconomic status and minority ethnic and racial groups and is the second leading cause of cancer mortality.[30] Squamous cell carcinoma and adenocarcinomas are the two most common histologic subtypes. Although the rates of squamous cell carcinoma have decreased, there has been an increase in incidence of adenocarcinoma and adenosquamous carcinomas in some countries like the United States.[31]

Patients with cervical cancer most commonly present with irregular or heavy bleeding, postcoital bleeding, vaginal discharge, or pelvic pain. The diagnosis is confirmed by cervical biopsy. Cervical cancer is staged clinically, and treatment depends on the stage.[32]

For most microinvasive early stage cervical cancer, simple hysterectomy is favored in lieu of radical hysterectomy. For selected patients, including those who wish to retain fertility, conization or radical trachelectomy may also be a consideration.

In other early stage disease, surgical approaches are equally effective as treatment with radiation therapy. Radical hysterectomy with either sentinel node biopsy or pelvic/paraaortic lymphadenectomy is the surgical approach of choice for patients who are unlikely to require adjuvant radiation. In cases of locally advanced disease with features such as clinically visible tumor greater than 4 cm or with invasion past the cervix to the pelvic sidewalls, vagina, rectum, bladder, or the pelvic and/or paraaortic lymph nodes, external beam radiation therapy with concomitant cisplatin is recommended over surgical removal. The risk of recurrence may be higher for patients who have radical hysterectomy performed using minimally invasive procedures, particularly when the size of a cervical lesion exceeds 2 cm.[33] Thus, the open approach is the standard of care. Studies are ongoing to identify risk factors that may support the use of minimally invasive techniques in selected patients.

Common Cervical Surgical Techniques

Conization/Loop Electrosurgical Excision Procedure

Removal of a portion of the cervix for diagnosis and treatment of cervical dysplasia can be achieved by a LEEP or CKC. A LEEP may be performed in the office, whereas a CKC is often done in the operating room (OR) due to need for increased exposure and

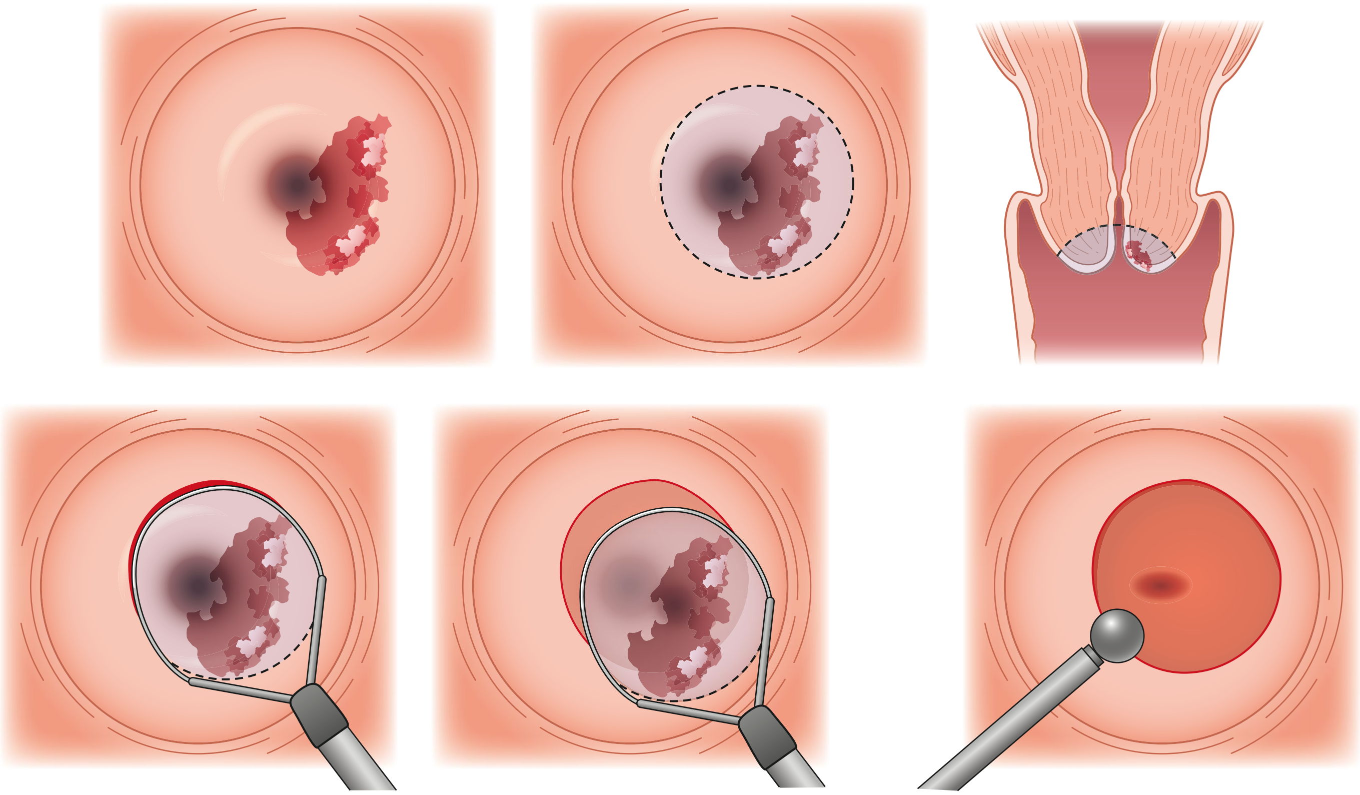

FIGURE 120.8 Loop electrosurgical excision procedure.

a longer operating time. A LEEP uses a wire loop that is heated by electrical current to excise the transformation zone of the cervix with the involved areas of CIN (Fig. 120.8). It is common practice to perform a small excision often called a “top hat” after removal of the first specimen. To perform a CKC, figure-of-eight retention sutures are placed at the 3 o’clock and 9 o’clock positions to ligate the descending branch of the uterine artery. After applying Lugol solution to the cervix to outline the areas of involvement and injecting lidocaine with epinephrine to reduce bleeding, a circumferential incision is made around the transformation zone and lesion using a Beaver blade. The specimen is grasped with Allis clamps to maintain orientation. The specimen is amputated using a scalpel or Mayo scissors. A marking stitch is placed at the 12 o’clock position. An endocervical curettage is performed above the cone biopsy. A running locked stitch or Sturmdorf stitch may be performed to evert the endocervical canal and achieve hemostasis.

Radical Hysterectomy/Radical Trachelectomy With Pelvic Lymphadenectomy

Radical hysterectomy refers to the excision of the uterus, parametria, and upper vagina. This can be performed via an open, minimally invasive, or vaginal approach. A shared decision regarding the surgical approach (open vs. minimally invasive) in selected cases. For open procedures, a transverse incision such as a Maylard or Cherney is often used to increase lateral exposure.

There are several different classification systems used to describe the extent of resection of tissues surrounding the cervix. The Piver-Rutledge-Smith classification is the oldest and most commonly used system.[34] It is divided into five types starting with type I (simple, extrafascial hysterectomy) up to type V (which describes removal of uterus en bloc with parametria, partial ureteral resection/bladder resection or both). Type II to IV varies on the amount of cardinal and ureterosacral ligaments and vagina that are removed as well as where the uterine artery is ligated. The modified radical hysterectomy that is most commonly used today is type III (Fig. 120.9). The principles of a radical hysterectomy include developing the paravesical and pararectal pelvic spaces, dividing the uterine arteries and veins, dissection of the bladder and ureters off the anterior cardinal ligament, and dissection of the rectum and pararectal tissues off the posterior cardinal ligament. The cardinal ligaments are then divided to allow an adequate sample of parametrium and margin. The ovaries are generally spared for premenopausal patients.

A radical trachelectomy may be an option for patients who desire future fertility with the International Federation of Gynecology and Obstetrics (FIGO) stage IA1 with lymphovascular space invasion, stage IA2 or stage IB1 disease. Most experts recommend this approach for malignant lesions 2 cm or less in diameter.[32] The procedure is performed like the radical hysterectomy with removal of the cervix, parametria, and upper vagina. However, the body of the uterus is preserved, a cerclage is placed, and the uterus is reattached to the superior vagina.

Pelvic lymphadenectomy is usually performed in conjunction with a radical hysterectomy or trachelectomy for early stage cervical cancer patients. Pelvic lymphadenectomy should include the nodes lateral and medial to the external iliac artery and vein from the bifurcation of the common iliac artery to the level of the deep circumflex iliac vein. Nodes from the obturator space between the external iliac vein and obturator nerve should also be excised. SLN mapping for small early stage tumors is an alternative to pelvic lymphadenectomy. Resection of paraaortic lymph nodes is not routinely performed, particularly if there is no evidence of metastasis in the paraaortic or pelvic nodes. When performed,

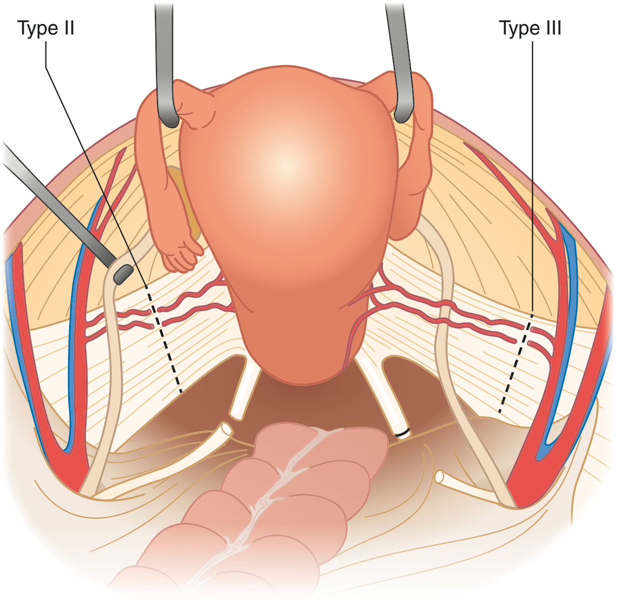

FIGURE 120.9 Type II/III radical hysterectomy. (From From Frederick PJ, Whitworth JM, Alvarez RD. Radical Hysterectomy for Carcinoma of the Uterine Cervix. *Global Libr Women's Med. [ISSN: 1756-2228]* 2011. doi:10.3843/GLOWM.10232)

paraaortic lymphadenectomy should be performed bilaterally by removing the nodes lateral to the common iliac artery and aorta from the bifurcation of the common iliac to the level of the inferior mesenteric artery.

COMMON UTERINE SURGICAL DISEASES AND PROCEDURES

Common uterine surgical diseases and procedures are listed in Table 120.4. A description of these diseases and management options follows.

Common Uterine Surgical Diseases

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) is one of the most common gynecologic complaints and conditions in the reproductive-age female. It is defined as bleeding that occurs in excess of or in addition to the normal menstrual cycle bleeding. A normal menstrual cycle should occur regularly between 24 and 38 days, with duration of flow between 4 and 8 days. Previously, AUB was often referred to as menorrhagia, menometrorrhagia, or dysfunctional uterine bleeding, but these terms have been replaced with a classification system aimed at identifying the cause of the excess bleeding. The PALM-COEIN system was established in 2011 as a result of work by the FIGO Working Group on Menstrual Disorders. Each letter in the acronym PALM-COEIN represents a condition, which is an etiology of AUB.[35] The PALM group includes structural entities that can be diagnosed with imaging modalities or histologic evaluation. These include polyps, adenomyosis, leiomyoma, hyperplasia, and malignancy. The COEIN group includes medical or nonstructural diagnoses. These are coagulopathy, ovulatory dysfunction, endometrial causes, iatrogenic causes (usually attributed to medications), and "not otherwise classified" for those patients without an obvious underlying etiology.

TABLE 120.4 Common Uterine Surgical Diseases and Procedures

DISEASE	PROCEDURE OPTIONS
Abnormal uterine bleeding	Endometrial ablation Hysterectomy
Uterine polyp	Hysteroscopic polypectomy
Uterine fibroids (leiomyomata)	Myomectomy Uterine artery embolization Hysterectomy
Adenomyosis	Hysterectomy
Endometrial cancer/ other uterine cancers	Hysterectomy/bilateral salpingo-oophorectomy with select sentinel node dissection or pelvic/ paraaortic lymphadenectomy

The initial workup for AUB includes a detailed history; a pelvic examination to assess for tenderness, mass, or uterine enlargement; a pregnancy test; laboratory evaluation of thyroid, blood count, prolactin level, cervical cancer screening if not up to date; screening for sexually transmitted infections; and a pelvic ultrasound. Screening for coagulation disorders is indicated if heavy bleeding has been present since menarche, there is a family history of coagulopathy, the patient is on a medication associated with abnormal bleeding, or there are signs and symptoms of other system bleeding (nosebleeds, easy bruising, etc.).

Endometrial biopsy, usually an office procedure, is indicated to rule out endometrial hyperplasia or malignancy in patients at elevated risk for these conditions. Patients age 45 or older with AUB, including intermenstrual bleeding, should undergo endometrial sampling. Patients younger than 45 years old with certain risk factors should also be biopsied. These risk factors include unopposed estrogen exposure, such as those with obesity and ovulatory dysfunction, with persistent AUB or AUB refractory to medical management, or an elevated familial risk of cancer.

Postmenopausal bleeding is not included in the PALM-COEIN classification system and is considered its own diagnosis. Although many causes of AUB in the reproductive-age female are physiologic, any bleeding in the postmenopausal female should be considered abnormal and requires thorough evaluation. The most common cause of abnormal bleeding in a postmenopausal female is atrophy, a thinning of the endometrial lining and vaginal tissue due to lack of estrogen. Without the lubrication and insulation that a thickened endometrial lining provides, the uterine cavity is susceptible to inflammation and infection.

The major concern with postmenopausal bleeding is an underlying malignant or premalignant condition. Of patients diagnosed with endometrial cancer, 90% of patients experience postmenopausal bleeding. Other causes of postmenopausal bleeding include uterine polyps, fibroids, adenomyosis, and medications (most commonly, hormone replacement therapies and anticoagulants). The initial evaluation, in addition to a thorough history and physical examination, includes a pelvic ultrasound and endometrial biopsy. If the endometrial thickness on pelvic ultrasound is 4 mm or less, endometrial biopsy may be avoided. However, recent data have shown that this ultrasound cutoff of 4 mm or less has led to under diagnosing endometrial cancer in Black patients.[36] An endometrial biopsy is indicated for endometrial thickness greater than 4 mm, suspected focal lesion on imaging, difficulty visualizing the endometrium, or persistent bleeding despite a normal ultrasound.[37]

Uterine Polyps

Uterine polyps, also called *endometrial polyps,* are an overgrowth of endometrial glands and stroma that either lie flat along the endometrial lining (sessile polyps) or project out into the cavity (pedunculated polyps). They have an inner "feeder vessel" that often allows them to be diagnosed by Doppler sonography. As discussed previously, they are a common cause of AUB or postmenopausal bleeding. There is large variability in polyp size from a few millimeters to several centimeters, with larger polyps being easier to detect. The majority of endometrial polyps are benign; however, up to 5% of polyps can undergo malignant transformation.[38] Factors associated with uterine polyp formation include increasing age, menopausal status, tamoxifen use, obesity, hypertension, polycystic ovarian syndrome, and familial hereditary cancer syndromes. In addition to AUB, endometrial polyps may be associated with an increased risk of early pregnancy loss.

Leiomyoma

Uterine leiomyomata, or fibroids, are the most common benign gynecologic tumors, affecting up to 70% of patients by age 50. There is a predominance in Black patients, and they experience earlier onset of fibroids, greater number, larger tumors, and more severe symptoms.[39] Fibroids are smooth muscle tumors that arise in the myometrium of the uterus. They can be located anywhere within the uterine wall and are often classified based on their location (Table 120.5).[35] Type 0 fibroids are located completely in the uterine cavity and are often attached with a stalk. They are called *pedunculated* or *intracavitary fibroids*. Types 1 and 2 are submucosal; type 1 fibroids involve less than 50% of the myometrium, whereas type 2 fibroids extend into the wall 50% or more. Types 3, 4, and 5 are intramural fibroids, located completely within the uterine wall with increasing subserosal contact as the numbers increase. Types 6 and 7 are subserosal (type 7 are pedunculated), whereas type 8 are cervical fibroids. Fibroids can be very small or very large and can be single or multiple. They are diagnosed with pelvic imaging, usually an ultrasound or magnetic resonance imaging (MRI).

Symptoms of fibroids, commonly abnormal bleeding, pelvic pain, or pressure-related symptoms from adjacent organs, are directly related to the location and size of the fibroid(s). The treatment options are also related to location and size of fibroids. Treatment options are medical or surgical, depending on the patient's desires and future fertility plans. Surgical treatments are discussed in the following section. Medical options are often directed at bleeding symptoms and include many contraceptive-type medications. Fibroids tend to grow in the reproductive years and regress in size with menopause, thus indicating a relationship between fibroid growth and ovarian hormones. Other risk factors include familial predisposition, obesity, and some dietary factors.[36]

TABLE 120.5 FIGO Classification System for Uterine Fibroids

TYPE	LOCATION	OPERATIVE REMOVAL APPROACH
0	Intracavitary	Vaginal or hysteroscopic
1	Submucosal	Hysteroscopic
2	Submucosal/intramural	Hysteroscopic or open/laparoscopic
3,4,5	Intramural	Open or laparoscopic
6	Intramural/subserosal	Open or laparoscopic
7	Subserosal/pedunculated	Open or laparoscopic
8	Extrauterine (parasitic, broad ligament, cervical, etc)	Open or laparoscopic

Adapted from Munro MG, Critchley HO, Broder MS, et al. FIGO classification system (PALM-COEIN) for causes of abnormal uterine bleeding in nongravid patients of reproductive age. *Int J Gynaecol Obstet.* 2011;113:3-13.

Adenomyosis

Adenomyosis is defined as the presence of endometrial glands and stroma within the myometrium and is considered a variant of endometriosis. Adenomyosis is found often with endometriosis or fibroids at the time of hysterectomy.[35,40] There is a molecular interaction between the displaced endometrial cells and the adjacent myometrial cells, which causes hypertrophy of the myometrium and inflammation. In some patients, this results in a heavier, enlarged uterus. The pathogenesis of adenomyosis is not clearly understood and may share some of its pathophysiology with endometriosis. Adenomyosis often coexists with uterine leiomyoma. Although adenomyosis is commonly a postsurgical diagnosis in that it is diagnosed by pathology, it can be clinically suspected and often identified on pelvic imaging.[40] On ultrasound or MRI, adenomyosis is seen as heterogeneity in the myometrium, a blurring of the junctional zone between the endometrium and myometrium, or the presence of "cysts" within the myometrial layer. Adenomyomas, which can be confused for uterine leiomyomata, are discrete masses of adenomyosis, which are seen as focal asymmetric thickening of the myometrium.

The prevalence of adenomyosis is estimated around 30% of patients of reproductive age with increasing prevalence in the later reproductive years. It is found more commonly in multiparous patients compared with nulliparous patients.[40] Symptoms of adenomyosis are heavy, painful periods, irregular bleeding, painful intercourse, and noncyclic pelvic pain. Some patients with adenomyosis will be asymptomatic. Adenomyosis is treated medically with nonsteroidal antiinflammatory drugs and hormonal contraceptives. A hysterectomy is the surgical intervention of choice for those patients who have failed medical management and do not desire future fertility.

Endometrial and Other Uterine Cancers

Endometrial cancer is the most common gynecologic cancer worldwide and is increasing in incidence and mortality.[25,28] Although the 5-year survival rate has been relatively unchanged at approximately 80%, it is the only cancer for which survival has decreased over the past four decades, and it is now the leading cause of gynecologic cancer death in the United States, with 67,880 new cases and 13,250 deaths estimated for the year 2024.

Black patients have the highest age-adjusted incidence of endometrial cancer.[28] Disparities in survival are marked between White and Black patients at 84% and 64%, respectively. Further, Black patients are more often diagnosed with more aggressive types and advanced stages and are less likely to be offered guideline concordant treatment compared with White patients.[41]

Suspected causes for the increasing incidence of endometrial cancer include the decline in hysterectomy performed for benign disease as well as other common risk factors that have increased in the population in general, such as age, obesity, and diabetes. Other contributory factors such as nulliparity, unopposed estrogen/tamoxifen, and hereditary syndromes, such a nonpolyposis colorectal cancer syndrome (Lynch syndrome), are important considerations. Patients with Lynch syndrome also have an increased risk for ovarian cancer, and age-appropriate risk-reducing hysterectomy with bilateral salpingo-oophorectomy should be a consideration in these patients after childbearing is complete.[42]

Postmenopausal or AUB are common presenting symptoms and may be the only symptom in patients with endometrial cancer. Evaluation should include a transvaginal pelvic ultrasound and endometrial biopsy or hysteroscopy with dilation and curettage. Most patients will have endometrioid adenocarcinoma on pathologic evaluation of biopsy samples. Other histologic types include serous carcinoma, clear cell carcinoma, and carcinosarcoma, all of which are associated with higher risk of extrauterine metastasis and recurrence and poorer long-term survival.

A pelvic MRI should be performed for patients with apparent early stage disease who are considering fertility-sparing hormonal therapy options. Approximately 15% of patients will present with symptoms and examination findings suggestive of more advanced stage disease. Abdominal pelvic computed tomography (CT) should be considered in addition to transvaginal pelvic ultrasound and endometrial sampling in these instances.

The general approach to surgical staging includes extrafascial hysterectomy with bilateral salpingo-oophorectomy with pelvic and paraaortic lymphadenectomy.[43] A minimally invasive approach (conventional laparoscopy or robotic assisted) has similar progression-free survival and overall survival to open approaches, and it has shorter hospital stay and operative adverse events.[44] Open and minimally invasive approaches for staging high-risk disease demonstrate similar outcomes and overall survival.

Surgical staging has both a prognostic role and a diagnostic role in identifying patients who need adjuvant treatment. Surgical staging for patients with early stage endometrial cancer has evolved over the past two decades. Evaluation for intraperitoneal metastasis and bilateral pelvic and paraaortic lymph node involvement remain key components of staging. Patients with low-risk endometrial cancer as defined by Mayo criteria (grade 1–2 endometrioid adenocarcinoma, 2 cm or less in diameter with less than 50% myometrial invasion and absence of extrauterine disease on intraoperative frozen section) have very low rates of metastasis and lymph node assessment may be omitted.[45]

SLN mapping with injection of indocyanine green into the cervix has replaced full lymphadenectomy and is an alternative to using the Mayo criteria because of the acceptable accuracy and lower risk of postoperative morbidity SLN biopsy.[43] Yet substantial disparities exist in its use between different patients of different race (7.0% Black, 9.4% non-Black), ethnicity (8.3% Hispanic, 9.5% non-Hispanic), insurance (6.0% uninsured, 9.5% insured), county density (3.7% rural, 9.8% metro), and income (7.0% bottom-quartile, 11.8% top-quartile).[46] These disparities in surgical approach may increase morbidity and delay adjuvant treatment for Black patients who are already diagnosed with more advanced disease.

Patients with more extensive extrauterine disease generally benefit from cytoreductive surgery similar to that done in patients with ovarian cancer.[43] For patients with localized recurrence, surgery may be indicated if no pelvic radiation was used. Pelvic exenteration is used for those patients with locally recurrent endometrial cancer who have had radiation.

Other rarer subtypes of uterine cancers include high-grade sarcoma, low-grade endometrial stromal sarcoma, and leiomyosarcoma. In the absence of clinically obvious nodal metastasis, lymphadenectomy is not required at the time of definitive hysterectomy.

Common Uterine Surgical Procedures

Hysteroscopy, Dilation and Curettage, Endometrial Ablation

Hysteroscopy is the placement of a small telescope into the uterine cavity for diagnostic purposes. It can be performed in the office in conjunction with a paracervical block or light anesthesia, or in the OR. If operative hysteroscopy is planned for the resection of a uterine lesion, general or regional anesthesia is required. After placement of a speculum, a single-tooth tenaculum is placed on the anterior lip of the cervix for gentle inferior retraction of the cervix to flatten the curve at the cervicouterine junction. The cervix is gently dilated. Normal saline solution is attached to a 12-degree or 30-degree hysteroscope for diagnostic hysteroscopy or operative hysteroscopy with bipolar current. With the distention media running, the hysteroscope is passed through the cervix and into the uterine cavity under direct visualization. The speculum can be removed once the scope is in the uterine cavity as it can impede mobility of the scope and impact visualization of the entire cavity or the execution of an operative procedure. Under pressure, the cavity is distended to allow the surgeon to visualize the fundus, both tubal ostia, the lower uterine segment, and the cervix. An operative hysteroscope will allow passage of scissors, graspers, electrosurgical equipment, and newer mechanical tissue removal system instruments for resection or biopsy of lesions. For global sampling, a curettage is performed after the hysteroscopy. The hysteroscope is first removed, and then a curette is passed through the cervix to the fundus. Gentle curettage is performed along all surfaces of the uterine cavity and the tissue is sent to pathology.

Operative hysteroscopy is the treatment of intrauterine pathology under direct visualization with the hysteroscope. Common operative hysteroscopy procedures include directed biopsy, polypectomy, myomectomy, lysis of intrauterine synechiae (adhesions), and endometrial ablation. Hysteroscopic polypectomy can be performed using a variety of mechanical instruments (Fig. 120.10). Commonly used instruments for polypectomy include a biopsy forceps and scissors, a mechanical tissue removal system, various electrodes such as loop electrode, and a polyp snare. The procedure for hysteroscopic myomectomy is like polypectomy and is reviewed in the section on hysteroscopic myomectomy. For uterine adhesions, scissors are used to lyse adhesions that connect the anterior and posterior walls of the uterine cavity.

Endometrial ablation is the destruction of the endometrial lining by heat or cold. A diagnostic hysteroscopy is performed to make sure the endometrial cavity appears normal without lesions. Any fibroids or polyps are removed. There are several types of nonresectoscopic or "global" endometrial ablation devices, which do not require hysteroscopic guidance. These disposable devices are deployed blindly into the uterine cavity. They have several safety mechanisms in place to both control the amount of heat or cold spread as well as stopping the device from activating if a proper seal is not detected.

Myomectomy

Myomectomy is the removal of uterine fibroids while still preserving the uterus in situ. Depending on fibroid size, location, and surgeon experience, myomectomy can be performed as an open abdominal procedure, laparoscopically, hysteroscopically, or vaginally.

Vaginal Myomectomy

Cervical/intracavitary fibroids that are protruding through the cervix and seen vaginally can be removed via this route.[47] They

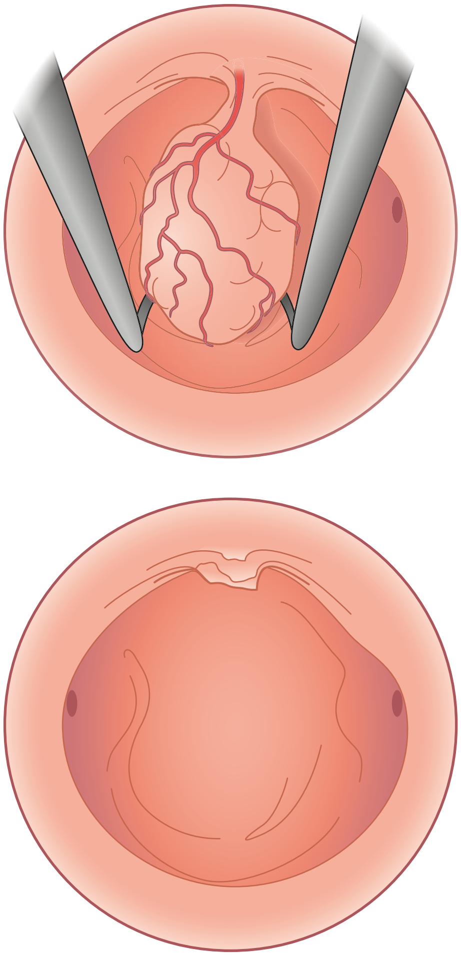

FIGURE 120.10 Hysteroscopic resection of a polyp.

often have a large vascular stalk that is attached in the endocervical canal or higher in the endometrial cavity. A hysteroscope can help determine the location of the attachment. The greatest risk of vaginal myomectomy is uncontrolled bleeding from the stalk, which often retracts when the myoma is amputated. There are several methods to reduce the risk of bleeding during vaginal myomectomy. At the beginning of the procedure, lateral sutures at 3 o'clock and 9 o'clock are placed in the proximal cervix to occlude the lower branch of the uterine artery. Dilute vasopressin can be injected at the stalk (usually 20 units in 100 cc of normal saline). One or two Endoloop sutures can be passed around the stalk and secured high with the transection of the stalk performed distal to the ligation. Transection can be performed sharply or with electrosurgery. If bleeding is unmanageable after removal, a hysteroscope with attached bipolar cautery should be available for intracavitary sources of bleeding or uterine packing with a Foley balloon can be performed.

Hysteroscopic Myomectomy

Type 0, type 1, and some type 2 fibroids can often be removed via operative hysteroscopy (see Table 120.5). There are two methods for removal: electrosurgery and a mechanical tissue removal system. Both should be performed by experienced hysteroscopists. Removal by electrosurgery is performed through an operative hysteroscope, with either monopolar or bipolar current. Most often, a small loop is used to shave the fibroid to its base. A polyp forceps is used to grasp the shaved tissues pieces to remove them from the endometrial cavity. With the mechanical tissue removal systems, gentle suction draws the fibroid to the end of the morcellator and the fibroid is cut and removed in small segments through the same suction. The cutting activity is either mechanical or electrosurgical, depending on the particular device. In both cases, the tissue is collected and sent to pathology.

One of the most important safety parameters in operative hysteroscopy, especially with myomectomy, is monitoring of intrauterine fluid deficit during the procedure. An isotonic solution such as normal saline or lactated Ringer solution is typically used with modern day bipolar resectoscopes. Hypotonic fluid, such as mannitol, was typically used with monopolar resectoscopes. A fluid management system, which closely measures fluid in and out of the hysteroscope, should be used and closely observed throughout the procedure. A large bolus of isotonic fluid during hysteroscopy increases the patient's risk of fluid overload and pulmonary edema. A large deficit of hypotonic fluid not only increases the risk of fluid overload but also increases the risk of electrolyte imbalances, particularly hyponatremia. Many gynecologic surgery societies have published recommended guidelines for fluid deficit, based on the use of isotonic or hypotonic solutions. A deficit of no more than 2500 cc is recommended for isotonic solutions, whereas 1000 cc is the maximum deficit for hypotonic solutions.[48] If a deficit limit is reached, the procedure should be terminated and the surgeon may repeat the surgery at a later date.

Laparoscopic and Open Myomectomy

The remaining fibroids (types 3–8) are removed via either the laparoscopic or the open approach (see Table 120.5). The steps are similar regardless of the approach. The most important step in a successful myomectomy is appropriate preoperative planning. A physical examination and appropriate imaging will help decide the best surgical approach and plan for uterine incision(s). MRI is the preferred imaging modality for planning a myomectomy as it provides more detail about fibroid location, number, and vascularity. The MRI will also help identify the path of the endometrial cavity which is an important aspect of planning uterine incisions.

At the time of surgery, the anatomy is examined and the orientation of the uterus in relation to the adnexal structures is noted. The uterine arteries, as reviewed in the anatomy section, run along the lateral sides of the uterus; thus, hysterotomy incisions should be made medially. The location of the adnexal structures are helpful in determining where the uterine arteries lie if the normal uterine anatomy is distorted by the fibroids. Dilute vasopressin (typically 20 units in 100 cc of normal saline) is injected into the serosal and myometrial layer overlying the fibroid until a blanching is noted.[49,50] An incision is made sharply, with monopolar current, or with a harmonic scalpel in the serosa overlying the fibroid and carried through the myometrium until the capsule of the fibroid is identified (Fig. 120.11). The fibroid is grasped, often with a tenaculum or penetrating towel clamp. Using blunt dissection, monopolar current, sharp dissection, or the harmonic scalpel, the fibroid is dissected from the adjacent myometrium while avoiding an incision directly into the myometrial layer. Hemostasis is maintained with judicious use of cautery or suture ligation. Once the myoma is completely dissected, the myometrial incision is closed with delayed absorbable suture, the number of layers determined by the depth of incision. Barbed suture is commonly used during this step. A final serosal suture layer is placed to approximate the hysterotomy edges and achieve

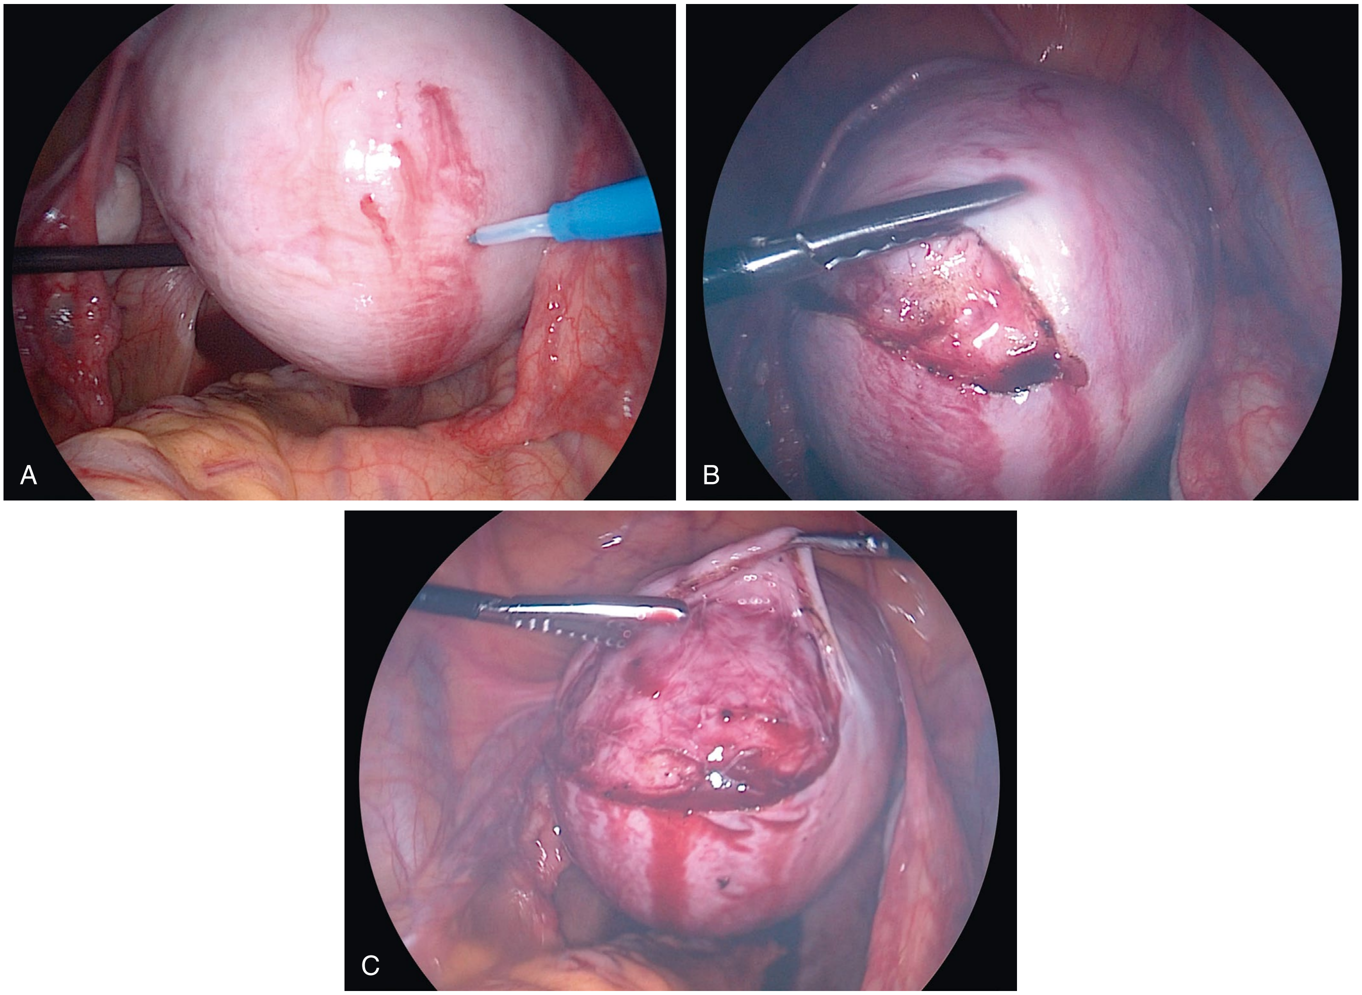

FIGURE 120.11 (A–C) Laparoscopic/open myomectomy.

hemostasis. Once all fibroids are removed, an adhesion barrier can be placed before abdominal closure.[51]

In addition to intramyoma injection of vasopressin, other hemostatic measures are available to control bleeding during open and laparoscopic myomectomy. Before incision, the surgeon can place misoprostol (usually 400–800 mcg) rectally. The misoprostol induces uterine contraction, which causes a tamponade effect on the smaller vessels within the myometrium. Another medical option is to give tranexamic acid (1000 mg given in an IV bolus) around the time of incision.[52] The antifibrinolytic affects prevent clot breakdown, and it is a well-tolerated medication. Intraoperative tourniquet placement is another option. During a myomectomy, a Penrose drain, pediatric feeding tube, or suture is placed around the lower uterine segment (after opening the broad ligament bilaterally and/or infundibulopelvic ligaments) to impede blood flow to the uterus during myoma removal.[53] This technique can be used laparoscopically or during an open procedure. Temporary laparoscopic vascular clips/clamps (such as bulldog clamps) can be used in a similar fashion on the uterine arteries and ovarian vessels.[54] These temporary tourniquet methods should be left on no longer than 90 minutes with at least 10 minutes of rest time between replacements.[53]

After successful myomectomy, the patient should be adequately counseled regarding future childbearing plans, risk of uterine rupture, and options for laboring. Patients who undergo myomectomy should wait at least 3 to 6 months before conceiving. They should consult their obstetrician about timing and method of delivery. Often patients with extensive myomectomies, or procedures that enter the endometrial cavity, will be offered prelabor cesarean sections to decrease their risk of a uterine rupture.[55]

Hysterectomy

Hysterectomy, by definition, is surgical removal of the uterus. There are several routes in which this can be accomplished, and there are also several options for patients and surgeons regarding type of hysterectomy and, if relevant, concomitant salpingectomy and oophorectomy. When considering hysterectomy, it is important to divide the anatomic approach into components that focus on the fallopian tubes and ovaries (when applicable), on the uterine corpus, and on the cervix and upper vagina (Fig. 120.12).

Total Abdominal Hysterectomy

A total hysterectomy is removal of both the uterine corpus and cervix. This can be accomplished via an open incision, vaginal incision, or minimally invasive techniques. For an open technique, also called a *total abdominal hysterectomy,* an abdominal incision is made that is either low transverse or vertical midline. The incision type is chosen based on the indication for the procedure, body habitus, surgical history, size of pathology, and

surgeon preference. The reproductive anatomy is identified, and any abnormalities are noted. The round ligaments should be grasped with a clamp laterally and divided either directly with electrocautery or ligated with a delayed absorbable suture and then divided medial to the suture. The anterior leaf of the broad ligament is then incised medially toward the level of the internal cervical os. This facilitates development of the bladder flap, which ultimately helps separate the bladder from the lower uterine segment allowing it to retract inferiorly.

If the fallopian tubes and ovaries are to be removed, the posterior leaves of the broad ligament are incised. After identifying the ureters, the ovarian vessels, which course in the infundibulopelvic ligament, are doubly clamped with curved Heaney or Zeppelin clamps and incised with curved Mayo scissors between the clamps. The remaining pedicles are doubly ligated. The specimen sides are ligated to prevent back bleeding. The remaining leaves of the posterior broad ligament are incised inferiorly to skeletonize the uterine vessels as they travel along the lateral edge of the uterus. If the fallopian tubes and ovaries are not being removed, two curved Kelly or Heaney clamps can be placed across the uteroovarian vessels, which are then divided and doubly ligated.

Surgical attention then focuses on the uterus and cervix. The bladder is further dissected off the cervix sharply with Metzenbaum or with electrocautery and retracted inferiorly. A curved Heaney or Zeppelin clamp is placed across the uterine vessels at the level of the internal cervical os, and the pedicle is cut and suture ligated. After further dissecting the bladder completely below the level of the cervix, a straight Heaney or Zeppelin clamp is placed on the remaining cardinal and uterosacral ligaments in serial steps bilaterally and the pedicles are cut and suture ligated. Once both sides are clear of tissue at the level of the external cervical os, the uterus and cervix can be separated from the upper vagina. This can be accomplished by placing curved clamps across the vagina medial to the prior pedicles just below the cervix from both sides to meet in the middle. Curved scissors cut just above the clamps to separate the uterus and cervix off of the vagina. Heaney transfixion stitches can be placed beneath the two clamps to ligate the vaginal corners and then interrupted figure-of-eight stitches can be used to close the vagina in the midline. Another method of colpotomy and vaginal cuff closure involves making a direct sharp incision into the vagina, just below the cervix. The incision is extended around the cervix with curved scissors until the cervix is completely removed. The edges of the upper vagina are gently grasped with Allis clamps to allow visualization. The colpotomy is then closed with running suture, interrupted sutures, or figure-of-eight sutures, with the lateral apex sutures incorporating the ipsilateral uterosacral ligament for apical support.

Minimally Invasive Hysterectomy

The steps for the minimally invasive route for hysterectomy are similar whether done with a conventional laparoscopic or robotic approach. However, instead of clamps and suture, all pedicles are secured and divided with electrocautery vessel sealing and cutting devices. For the laparoscopic approach, port placement and configuration are dependent on the surgeon and the patient's anatomy. Typical trocar placement for gynecologic surgery includes any combination of an umbilical trocar, bilateral lower quadrant trocars, and a suprapubic or upper quadrant trocar for assistance. For a large, bulky uterus, trocars can be placed slightly higher in the abdomen and often more ports are used. The camera is commonly placed through the umbilical port, and a 0-degree or 30-degree scope is used. A robotic approach for hysterectomy for benign conditions is similar to the laparoscopic approach but costs are higher.[56] Trocars for the robotic approach to hysterectomy are placed per usual robotic guidelines.

For assistance from the vaginal side, a uterine manipulator with attached colpotomizer cup or a cervical ring should be placed and secured at the cervix. This instrument is the key to identifying the cervicovaginal fornices, avoiding a urinary tract injury, and helping to delineate where the colpotomy should be made.

A minimally invasive hysterectomy proceeds as described for the open approach. Once the uterine vessels and the cardinal and uterosacral ligaments are divided, a colpotomy is then completed along the colpotomizer cup or cervical ring with monopolar energy (usually Endoshears or a monopolar hook) or ultrasonic energy. The uterus, cervix, and adnexa (when applicable) can usually be delivered through the vagina. A sponged-filled glove or pneumooccluder balloon is placed in the vagina and inflated to prevent egress of carbon dioxide while the colpotomy is closed with an absorbable or barbed suture generally with a running stitch. Alternatively, the cuff can be closed via a vaginal approach with interrupted figure-of-eight sutures.

Supracervical Hysterectomy

A supracervical or "subtotal" hysterectomy is the removal of the uterine corpus while leaving the cervix in situ. This procedure is the least preferred route of hysterectomy but may be required and is sometimes driven by patient preference. The procedure can be performed via the open or minimally invasive routes and follows the same steps as a total hysterectomy up to the point of the uterine artery ligation. After uterine artery ligation at the level of the internal cervical os, the body of the uterus is amputated from the cervix with curved scissors, electrocautery, or ultrasonic energy. The remaining endocervix and cervical stump are cauterized. The cervical stump is closed with figure-of-eight sutures for hemostasis. Cervical cancer screening must continue per guidelines. A contraindication to this procedure is malignant or premalignant disease of the uterus or cervix.

Vaginal Hysterectomy

Vaginal hysterectomy is one of the earliest reported gynecologic surgeries, and the steps are mostly unchanged since its introduction. The steps of a vaginal hysterectomy are in opposite order than those of an abdominal or laparoscopic hysterectomy, with the colpotomy being done first and the cornual pedicles next to last. For a vaginal hysterectomy, the patient is placed in a high lithotomy position. A paracervical block may be performed with dilute vasopressin or lidocaine with epinephrine for hemostasis. With traction on the cervix with a tenaculum, a circumferential incision is made around the cervix where the vaginal epithelium merges with the cervix. This is performed sharply or with electrocautery. The posterior peritoneal fold is grasped and placed on downward traction, and the posterior cul-de-sac is entered sharply with curved scissors. This incision is extended laterally, and the uterosacral ligaments are identified bilaterally. The uterosacral ligaments are clamped with curved Heaney or Zeppelin clamps, the ligaments incised off the posterior cervix with curved scissors, and the pedicles ligated with delayed absorbable suture and left tagged for later identification.

A long-weighted speculum is placed through the vagina, below the cervix, and into the posterior cul-de-sac. Attention is then turned anteriorly where the vaginal epithelium is lifted anteriorly, and the bladder is dissected off the cervix to the level of the peritoneum. Once the anterior peritoneum is identified, it is grasped and incised sharply. A right-angle retractor is then passed through this incision to retract the bladder anteriorly away from the uterus for the remainder of the hysterectomy. In serial bilateral steps, a curved clamp is placed laterally to clamp, divide, and ligate the cardinal ligaments and uterine vessels.

With each sequential pedicle, the uterus is further delivered inferiorly into the vagina. The final pedicles include the cornual structures, which include the round ligament, fallopian tube, and uteroovarian ligament. A curved clamped is placed across the cornua under direct visualization, making sure to include each cornual structure and to avoid trapping bowel. The pedicle is cut inferiorly to the clamp, freeing the uterus and cervix. This pedicle is doubly ligated and closely inspected for hemostasis before allowing it to retract superiorly out of view. A similar approach is employed if the ovaries and fallopian tubes are to be removed where the clamp is placed across the ovarian vessels.

The pelvis is examined for hemostasis at each pedicle site. The edges of the colpotomy are grasped with Allis clamps, with care to include the peritoneal layer in the closure. Angle stitches are placed first, incorporating the uterosacral ligaments tagged previously. The remainder of the colpotomy is closed horizontally with a delayed absorbable suture in either running, figure-of-eight, or interrupted sutures.

Elective Bilateral Salpingo-Oophorectomy and Opportunistic Salpingectomy

Unilateral or bilateral salpingo-oophorectomy can be done at the time of hysterectomy but should be reserved for those situations in which there are clear indications for removal. Elective salpingo-oophorectomy, particularly in patients below the age of 50, carries an increase in long-term cardiovascular and neurologic morbidity and mortality, especially if they do not receive hormonal replacement.[57] Routine opportunistic full salpingectomy is now recommended at the time of hysterectomy as a means of potentially reducing the risk of ovarian cancer.[58] These procedures are described in the following section on fallopian tubes and ovaries.

Postoperative Cystoscopy After Hysterectomy

Many gynecologic surgery organizations advocate an immediate postoperative cystoscopy at the conclusion of hysterectomy to assess the integrity of the bladder and ureters.[59] This is easily accomplished with a 30-degree or 70-degree cystoscope and sterile water or saline distention fluid. The urinary catheter is removed, and the scope passed through the urethra and into the bladder. The bladder should be fully distended so that the entirety of the dome is visible. The surgeon assesses for suture, foreign body, lesions, and defects. Additionally, both ureteral orifices are assessed for adequate efflux of urine.

Sentinel Node Biopsy and Lymphadenectomy for Endometrial Cancer

To mitigate complications associated with pelvic and paraaortic lymphadenectomy, SLN mapping is emerging as a preferred strategy for those patients with early stage endometrial cancer undergoing hysterectomy and bilateral salpingo-oophorectomy.[43] The preferred method is by injecting indocyanine green superficially (1–3 mm) and deep (1–2 cm) into the cervix at the 3 o'clock and 9 o'clock positions. Dye is traced to the involved nodes, which are commonly located in and along the pelvic iliac vessels but can also locate in the presacral or paraaortic regions. Sentinel nodes should be excised and subjected to ultrastaging, which includes serial sectioning and cytokeratin immunohistochemical staining.

Pelvic and paraaortic lymphadenectomy for early stage endometrial cancer patients who do not meet Mayo criteria should be completed in a setting where the side-specific sentinel node is not identified or where SLN mapping capabilities do not exist. Pelvic lymphadenectomy should include the nodes lateral and medial to the external iliac artery and vein from the bifurcation of the common iliac artery to the level of the deep circumflex iliac vein. Nodes from the obturator space between the external iliac vein and obturator nerve should also be excised. Paraaortic lymphadenectomy should be performed bilaterally by removing the nodes lateral to the common iliac artery and aorta from the bifurcation of the common iliac to at least the inferior mesenteric artery and higher toward the renal artery in the setting of higher risk malignancies such as serous carcinoma.

COMMON FALLOPIAN TUBE/OVARIAN SURGICAL DISEASES AND PROCEDURES

Common fallopian tube/ovarian surgical diseases and procedures are listed in Table 120.6. A description of these conditions and management options is as follows.

Common Fallopian Tube/Ovarian Surgical Conditions

BRCA Mutation Carrier

Patients who harbor a germline mutation in the *BRCA1* or *BRCA2* genes have a 72% and 69% risk of breast cancer by age 80 and a 44% and 17% risk of ovarian cancer by age 70, respectively.[60,61] The list of genes that increase the risk of breast and ovarian cancer when mutations exist continues to evolve. Notable genes, which infer increased risk of ovarian cancer, include *BRIP1, RAD51C, RAD51D*, and the mismatch repair genes. Guidelines exist that detail criteria for genetic counseling and single gene versus multipanel gene testing.[61] Patients who harbor a deleterious mutation in the *BRCA1* or *BRCA2* genes are candidates for more intense screening or chemoprevention strategies should fertility be desired. Risk-reducing salpingo-oophorectomy is recommended between the ages of 35 and 40 in patients with a *BRCA1* mutation and between the ages of 40 and 45 in patients

TABLE 120.6 Common Fallopian Tube/Ovarian Surgical Diseases and Procedures

DISEASE	PROCEDURE OPTIONS
BRCA mutation carrier	Risk-reducing bilateral salpingo-oophorectomy
Desires sterilization	Pomeroy partial salpingectomy Salpingectomy
Ectopic pregnancy	Partial salpingectomy Salpingostomy
Torsion	Detorsion
Endometrioma	Cystectomy Unilateral salpingo-oophorectomy
Benign ovarian mass	Cystectomy Unilateral salpingo-oophorectomy
Malignant ovarian neoplasms	Bilateral salpingo-oophorectomy, total hysterectomy, staging with early stage disease, debulking with late stage disease Unilateral salpingo-oophorectomy and staging with early stage disease and desire for future fertility

with a *BRCA2* mutation. Risk-reducing salpingo-oophorectomy in patients with a BRCA mutation has been demonstrated to reduce the risk of ovarian cancer by at least 80% and to reduce the risk of breast cancer by at least 50%, albeit recent studies suggest the reduction in breast cancer benefit is primarily noted in *BRCA1* mutation carriers.

Desires Sterilization

Sterilization is the most common method of contraception among married couples and twice as many couples choose female partner sterilization over male sterilization. Physicians should carefully counsel patients about the permanence of female sterilization particularly in light of long-acting reversible contraceptive measures, which are as effective birth control measures as permanent sterilization. Historical studies have demonstrated that patient race, ethnicity, and socioeconomic status have affected physician attitudes and practices with respect to counseling about reversible versus permanent counseling. Respect for an individual female's reproductive autonomy should be the primary guiding principal when discussing sterilization options. These discussions should also include informing the patient that male sterilization incurs less risks and is more effective than female sterilization and that the rates of failure of tubal sterilization are reported to be overall less than 2%. Physicians should also note that approximately 14% of patients express regret after sterilization. Patients at risk for regret include those of color, of young age, and after a recent pregnancy event. A fully informed shared decision model is key in discussing sterilization options with patients (Fig. 120.13).

Ectopic Pregnancy

The rate of ectopic pregnancy is about 1% to 2% that of live births and is potentially life threatening. Over 90% occur in the fallopian tube. Risk factors for an ectopic pregnancy include a history of ectopic pregnancy, pelvic inflammatory disease, infertility, use of an intrauterine device, smoking, and tubal ligation. Patients often present with nonspecific abdominal or pelvic pain and vaginal bleeding symptoms and on examination may be found to have a tender abdomen, cervical motion tenderness, or an adnexal mass. Patients with a ruptured ectopic pregnancy may present emergently with signs and symptoms of hypovolemic

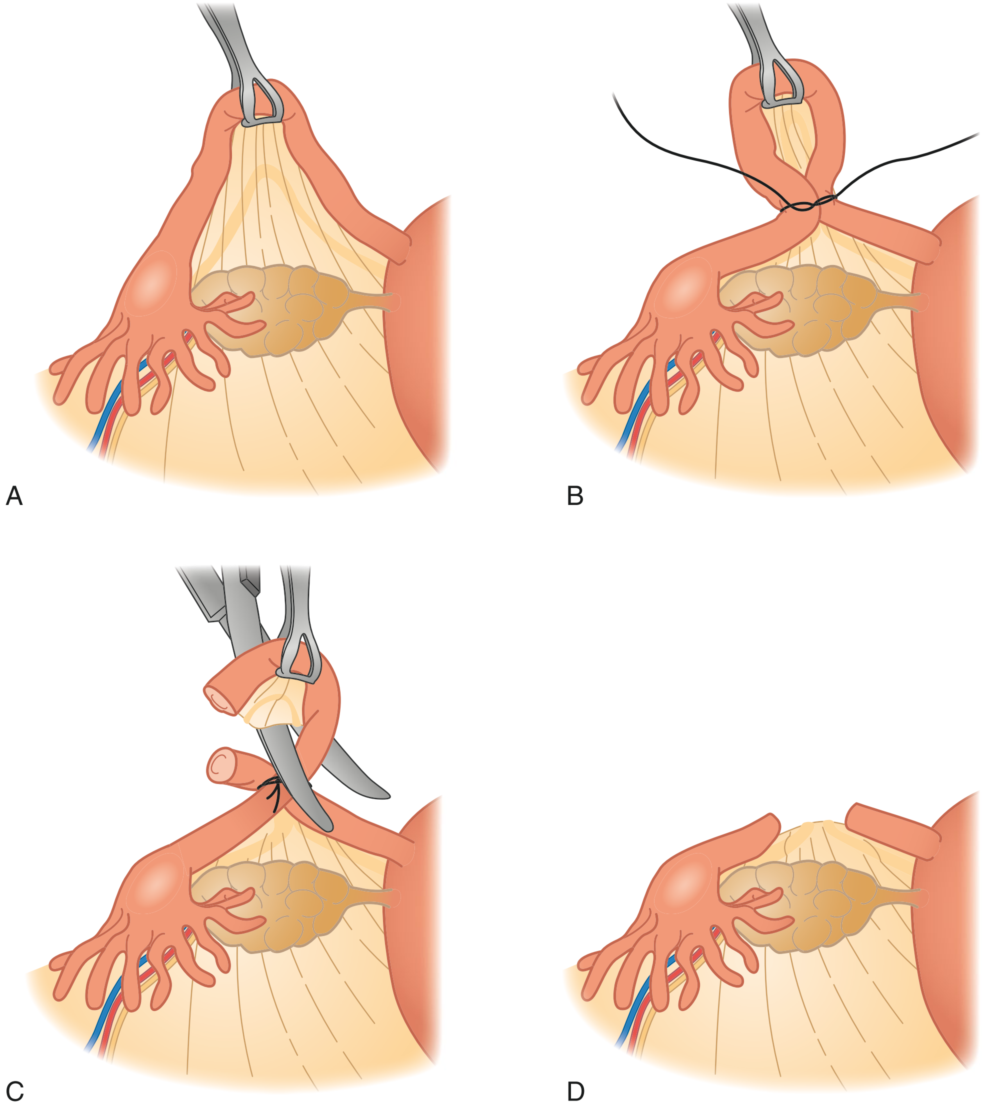

FIGURE 120.13 (A–D) Pomeroy tubal sterilization.

shock. A quantitative beta human chorionic gonadotropin (β-HCG) and transvaginal ultrasound should be expeditiously performed in patients who present with symptoms and signs suggestive of a potential ectopic pregnancy. The presence of a tubal ectopic with a fetal heartbeat or an inhomogeneous or noncystic adnexal mass (known as a *blob sign*) has high sensitivity for diagnosing an ectopic. Medical management with intramuscular methotrexate is an option for patients with a stable ectopic pregnancy for whom no medical contraindications exist. Surgical intervention is required in a patient who is hemodynamically unstable, has a persistent ectopic despite medical management, or has contraindications to medical management.

Torsion

Ovarian torsion occurs when the ovary, often together with the fallopian tube, twists on its attachments to other structures in the pelvis and compromises its blood supply. It accounts for 3% of all gynecologic emergencies. It occurs most commonly in patients of reproductive age, and the most common risk factor is the presence of an ovarian cyst or tumor. Patients with ovarian torsion generally present with acute-onset sharp unilateral pelvic pain. Nausea may also accompany the pain symptoms. Common signs on physical examination include unilateral lower abdominal pain and adnexal tenderness. The diagnosis may be facilitated with transvaginal Doppler ultrasound. Imaging studies may demonstrate an enlarged ovary with a twisted vascular pedicle and diminished arterial or venous blood flow. Of note, Doppler vascular flow is not always absent in torsion, and the diagnosis in this setting must be made on the basis of clinical suspicion. Ovarian torsion warrants urgent surgical intervention, and often the diagnosis is not confirmed until the ovary and fallopian tube are visualized intraoperatively.

Endometrioma

An endometrioma is an ovarian cyst often associated with peritoneal endometriosis, a condition where endometrial tissues exist outside of the endometrium. An endometrioma frequently consists of endometrial epithelium and stroma and is often called a *chocolate cyst* due to the dark brown, thick, and tarry hemosiderin-laden fluid it contains. Most patients with endometriomas are of reproductive age and will often present with symptoms of endometriosis. Common endometriosis symptoms include pelvic pain, dysmenorrhea, dyspareunia, and/or infertility. Some patients with an endometrioma are asymptomatic. Physical examination may demonstrate a painful adnexal mass and other signs of endometriosis, such as cul-de-sac nodularity. Transvaginal ultrasound is useful in detecting endometriomas. Typical sonographic findings associated with an endometrioma include a unilocular cyst with low-level echogenicity representing old blood (commonly termed *ground-glass* feature). Many patients with the presumptive diagnosis of endometriosis will be managed medically depending on the degree of symptoms and the desire for fertility. Larger endometriomas (>4 cm) are generally refractory to medical management, and laparoscopic excision is considered the treatment of choice. Although there has been concern that excision of an endometrioma might damage ovarian reserve, excision is preferred over drainage particularly in patients with pelvic pain symptoms, infertility, or suspicion for a neoplasm. Excision of the cyst also decreases the chance of the endometrioma recurrence.

Benign Ovarian Masses and Neoplasms

Most benign ovarian masses tend to be functional follicular or corpus luteum cysts, which in general are asymptomatic and rarely exceed 5 cm in diameter. The most common benign ovarian neoplasms include cystic teratomas (commonly known as *dermoid cysts*), serous or mucinous cystadenomas or cystadenofibromas, and fibromas or fibrothecomas. Many patients with a benign ovarian neoplasm will be asymptomatic, but some will experience pelvic pain. Most benign pelvic masses are noted to be smooth, mobile, and of various dimensions on pelvic examination. Rarely, will there be clinical signs of ascites. Evaluation should include transvaginal ultrasound to delineate the size and features of an adnexal mass because each neoplasm has distinct sonographic findings. Select tumor markers such as a cancer antigen 125 (CA125), β-HCG, alpha-fetoprotein (α-AFP), inhibin A and/or inhibin B, or lactate dehydrogenase (LDH) should be obtained depending on the clinical scenario and concern for a malignancy.

Conservative management with serial observation and management of symptoms, if present, of a patient with a functional ovarian cyst is advised. Surgical intervention, generally using a laparoscopic approach, is required for patients with a persistently symptomatic suspected benign ovarian neoplasm. Laparoscopic ovarian cystectomy is appropriate for a dermoid cyst or fibroma regardless of size, based on the surgeon's skill set. Oophorectomy is often required with larger dermoid cysts and with cystadenomas that replace the entire ovary. Laparotomy is generally reserved for much larger benign ovarian neoplasms, for when the diagnosis is equivocal, and if ovarian or fallopian tube malignancy is higher on the differential. Laparotomy should also be considered in the setting of a tuboovarian abscess that is refractory to antibiotics and image-guided drainage. Consultation with a gynecologic oncologist should be considered in settings when a cancer is suspected or when complex surgical intervention is anticipated.

Malignant Ovarian Neoplasms

Ovarian cancer is one of the deadliest gynecologic malignancies in part because it is often diagnosed at advanced stages of disease.[28,62] For patients with advanced epithelial ovarian cancer, examination will often demonstrate abdominal distention from ascites; evidence of carcinomatosis on abdominal examination; and a firm, nodular, fixed pelvic mass. The majority of patients with advanced stage ovarian cancer have high-grade serous carcinoma, which is now thought to originate in the fallopian tube in the majority of cases.[63] Endometrioid and, less frequently, low-grade serous carcinoma are other subtypes noted in patients with advanced stage disease. Other malignant ovarian neoplasms can originate from germ cells, stromal cells, or other epithelial cells from the ovary. Patients with a malignant ovarian neoplasm may present with nonspecific bloating or abdominal pain, early satiety, other nonspecific intestinal symptoms, and urinary frequency. On examination, patients with a germ cell, stromal cell, or early stage epithelial tumor might be found to have abdominal pain and an adnexal mass on pelvic examination with no obvious clinical evidence of metastasis.

CT examination of the chest, abdomen, and pelvis and tumor markers will help narrow down the differential to an ovarian or fallopian tube malignancy and demonstrate the extent of disease. Germ cell tumors are more common in younger patients, and relevant tumor markers should include a β-HCG, LDH, and AFP. For older patients with a suspected epithelial tumor, a CA125, carcinoembryonic antigen, and CA19-9 are most useful. In patients with a stromal tumor, an inhibin and select hormone tests may be of use, particularly when there is evidence of a hormonally functional mass. Recent breast or colon screening results in patients age 40 and above may help exclude metastatic breast or colon cancer from the differentiation in this clinical scenario.

Primary surgical debulking with staging has been the traditional approach to patients with a suspected malignant ovarian neoplasm. This approach is the preferred strategy in patients with clinical evidence of early stage disease. Surgery should be fertility sparing in the setting of a young patient with a germ cell tumor or low-grade epithelial tumor. Primary debulking should be considered in the setting of advanced stage epithelial cancer when the patient is medically fit and optimal (<1 cm residual disease and preferably no residual disease) surgical resection is anticipated. Meta-analyses comparing chemotherapy before debulking surgery (neoadjuvant chemotherapy [NACT]) with primary debulking surgery (PDS) followed by chemotherapy reveal a possible decrease in risk of serious adverse events, such as bowel resection, with NACT, but show no advantage in primary survival outcomes in patients with advanced disease.[64]

Referral to a gynecologic oncologist is useful in helping to make the decision to consider primary debulking versus NACT and interval debulking. In an otherwise fit patient with advanced stage disease, clinical features such as examination, CA125 level, and CT findings can inform the decision. Laparoscopic assessment using scoring systems have also been developed to facilitate the decision to proceed with primary debulking versus NACT. For select patients with recurrence, a secondary or beyond surgical resection may also provide some benefit. Patients who benefit the most from secondary debulking might include those with a long tumor-free interval and with evidence of isolated disease and no ascites.

Common Fallopian Tube/Ovarian Surgical Procedures

Tubal Sterilization

Tubal sterilization is most commonly performed via a laparoscopic approach but can also be performed via a mini-laparotomy or transvaginally. Opportunistic complete salpingectomy has increased as the preferred method for patients undergoing tubal sterilization because the fimbriated end of the fallopian tube has been shown to serve as the originating site for high-grade serous ovarian carcinoma.[58,63] For this procedure, the fallopian tube is elevated, and small windows are made in the avascular areas within the mesosalpinx. The small vessels providing blood supply to the fallopian tube are ligated or cauterized, and the fallopian tubes are excised where they insert into the uterine cornua.

Other commonly used techniques for tubal sterilization include the use of mechanical occlusive devices such as clips or rings and tubal cauterization. Technical failures and minor morbidity are noted more frequently with ring occlusion compared with clip occlusion. In general, a bipolar cautery device is used when cauterization of the tube is performed. Surgeons should ensure that a 2-cm portion of the mid fallopian tube is cauterized when this procedure is performed.

Salpingectomy/Salpingostomy for Ectopic Pregnancy

Surgical intervention is required for those patients with an ectopic pregnancy who fail medical management or who present with acute rupture of an ectopic. In general, a laparoscopic approach is preferred and can be used even in the setting of a large hemoperitoneum. Surgical options include a partial salpingectomy or salpingostomy (Fig. 120.14). Randomized trials have demonstrated no difference in the rates of subsequent ectopic pregnancies or intrauterine pregnancy.[65] In general, partial salpingectomy is the preferred approach when severe fallopian tube damage is noted and in cases in which there is significant bleeding from the proposed surgical site. The technique for salpingectomy mimics that done for tubal sterilization. Specifically, the portion of the fallopian tube is elevated and the fallopian tube proximal and distal to the ectopic is cauterized and incised. The mesosalpinx beneath the involved portion of the fallopian tube is cauterized and divided. The specimen is then forwarded for pathologic confirmation of an ectopic.

Salpingostomy should be considered in patients who have an ectopic pregnancy that has not ruptured, who desire future fertility but have damage to the contralateral fallopian tube, and in whom removal of the fallopian tube would require assisted reproduction

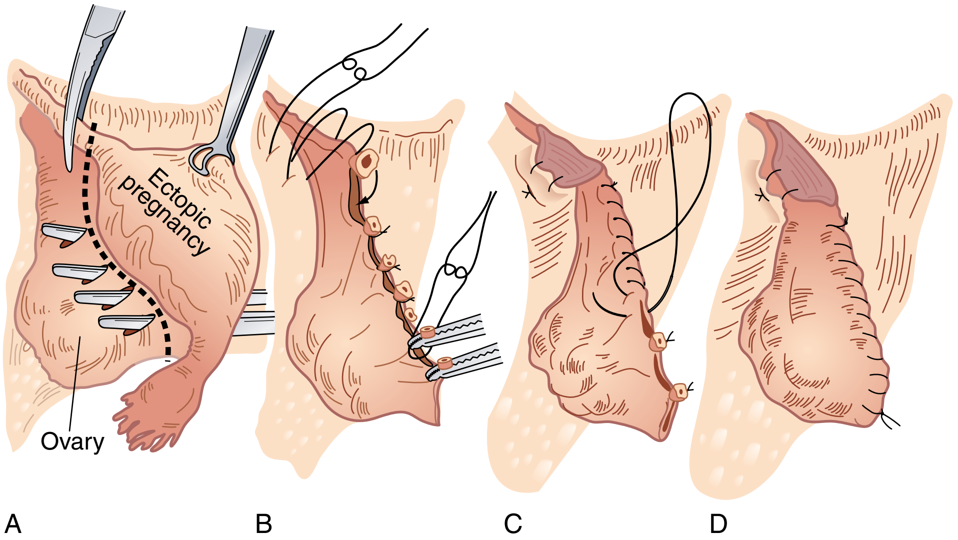

FIGURE 120.14 Salpingectomy. (A) Tube is excised from the cornual portion across the mesosalpinx to the fimbria. (B) Pedicles are tied, peritoneal lining is reestablished, and cornual portion of the tube is buried into the posterior segment of the uterine cornu. (C) Mesosalpinx is reperitonealized. (D) Mesosalpinx is closed and the procedure completed. (Adapted from Mitchell CW, Wheeless CR. *Atlas of Pelvic Surgery*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1997.)

for future childbearing. Salpingostomy involves injecting the involved fallopian tube with vasopressin and then creating a linear incision in the area involved with the ectopic pregnancy. The products of conception are then flushed out with a suction irrigator. There is no need to suture the salpingostomy site as it will heal well by secondary intention. When salpingostomy is performed, it is important to monitor the patient with serial β-HCG levels to ensure resolution of ectopic trophoblastic tissue.

Ovarian Detorsion

A diagnostic laparoscopy is the preferred surgical approach to confirm the suspicion of an ovarian torsion. In general, the involved ovary, and often fallopian tube, are noted to be twisted on its vascular supply (Fig. 120.15A). They often appear edematous and darkened as a result of vascular and lymphatic congestion and may seem nonviable. Detorsion rather than salpingo-oophorectomy is the procedure of choice because over 80% of patients have been noted to have normal ovarian function after this procedure (see Fig. 120.15B). The procedure involves untwisting the involved adnexa twisted vascular pedicle. Ovarian cystectomy may accompany detorsion when an ovarian cyst or benign ovarian neoplasm is noted. The risk of recurrence after detorsion appears small and oophoropexy has not been proven to reduce that risk.

Ovarian Cystectomy

Ovarian cystectomy is most often employed for patients with an endometrioma, a torsed ovary with a large benign ovarian cyst, a benign neoplasm such as a cystadenoma or dermoid, or a borderline tumor of the ovary. This technique is most appropriate for patients in whom retaining fertility is critical and in whom there appears to be residual normal ovary. Cystectomy is indicated for endometriomas over 4 cm and has been demonstrated to improve fertility over an incision and drainage procedure. Though cystectomy carries a higher risk of recurrence in borderline tumors of the ovary when compared with salpingo-oophorectomy, overall survival is not compromised.[66]

A laparoscopic approach is preferred in most cases for which ovarian cystectomy is planned. The surgical technique involves incising the ovarian surface over the ovarian cyst and using preferably mechanical or hydrodissection to completely excise the ovarian cyst (Fig. 120.16). Electrocautery or suturing may also be required to control areas of bleeding. Excision of an endometrioma can be quite difficult and ovarian reserve is often compromised postoperatively.

Salpingo-Oophorectomy

Salpingo-oophorectomy, unilateral or bilateral, is the procedure of choice for a number of clinical indications. Most often, this procedure is accomplished for a benign ovarian mass, which involves the entire ovary. Other indications include risk-reducing salpingo-oophorectomy for patients with a BRCA mutation, chronic pelvic pain with severe endometriosis or adhesive disease, or a malignant ovarian neoplasm. The procedure is most often completed using laparoscopy. Laparotomy is advised in situations when a patient may have had history of extensive pelvic surgery and significant

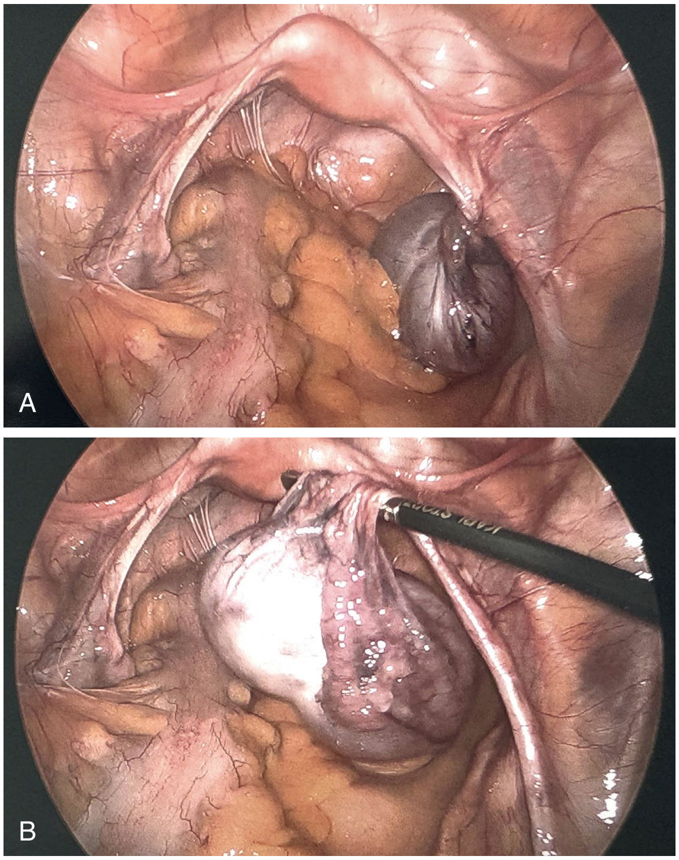

FIGURE 120.15 (A) Ovarian torsion. (B) Ovarian detorsion.

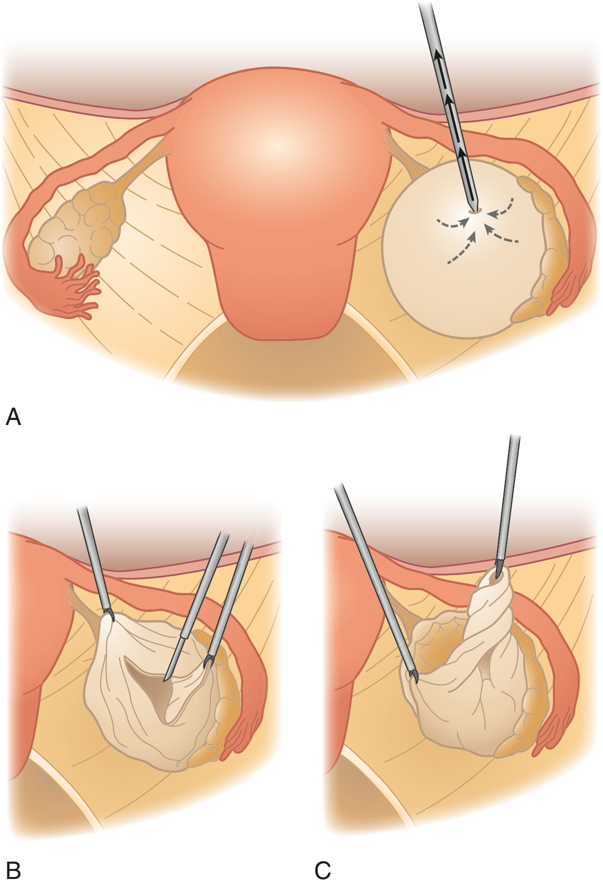

FIGURE 120.16 (A–C) Cystectomy.

pelvic adhesive disease is suspected, a mass is of a significant size or configuration that would make removal by laparoscopic technique difficult, or a malignancy is suspected.

The surgical technique for salpingo-oophorectomy, whether performed by laparoscopy or laparotomy, involves cauterization or ligation of the ovarian vessels contained within the infundibulopelvic ligaments lateral to the ovary and fallopian tube and cauterization or ligation of the uteroovarian vessels medial to the ovary and fallopian tube (see Fig. 120.12D). For risk-reducing salpingo-oophorectomy, it is important to ligate the ovarian vessels at least 2 cm lateral to the ovary and fallopian tube so that no residual ovary or fallopian tube is left behind. It is also important to obtain abdominal pelvic washings during that procedure and inform the pathologist that the procedure is being performed for a patient with a BRCA mutation so that appropriate serial sectioning of the specimens is performed. These steps are important because approximately 5% of patients with a BRCA mutation will be noted to have an occult ovarian or fallopian tube cancer.

Another key surgical principle in salpingo-oophorectomy includes identification of structures within the pelvis that are at risk of injury when the procedure is performed. Perhaps the most important of these structures is the ureter, which courses over the bifurcation of the common iliac artery close to the infundibulopelvic ligament. It is important to identify the ureter either via a transperitoneal or retroperitoneal approach. The ovary and fallopian tube should be lifted anteriorly and displaced as far from the ureter as possible before ligating the ovarian vessels. In scenarios where the ovary or fallopian tube are involved with pathology such as a mass or endometriosis that impedes easy separation of the structures from the ureter, ureterolysis should be performed. Ureterolysis via a retroperitoneal approach allows for safer ligation of the ovarian vessels. It is also important to identify and carefully lyse any adhesions of the small or large intestine to prevent injury to the bowel. Lastly, it is important to be aware of the position of the adnexa's relationship to the external iliac vessels. Incising the posterior broad ligament (and in some instances the round ligament) facilitates development of the pararectal space and separation of the adnexa from the pelvic sidewall vessels. This procedure also helps facilitate identification of the ureter via a retroperitoneal approach.

Fallopian Tube/Ovarian Cancer Cytoreduction

Approximately 10% to 15% of patients with ovarian cancer are found clinically to have disease apparently confined to the ovary. Early stage disease is more common in patients with germ cell tumors of the ovary, stromal cell tumors of the ovary, and certain epithelial ovarian tumors (e.g., mucinous, clear cell). Surgical staging of early stage ovarian cancer involves removal of both ovaries and fallopian tubes, hysterectomy, abdominal pelvic washings, excision of suspicious peritoneal nodules or selective random peritoneal biopsies, infracolic omentectomy, and pelvic and paraaortic lymphadenectomy.[62] In certain circumstances, such as in the case of germ cell tumors of the ovary, fertility preservation should be considered, and removal of the uninvolved ovary and uterus is not necessary.

Most patients affected by epithelial ovarian or fallopian tube cancer have advanced stage disease and usually present with the constellation of findings including pelvic mass(es), omental metastasis, intraperitoneal carcinomatosis, and ascites. The primary surgical goal in this scenario shifts from staging to optimal cytoreduction. The definition of optimal cytoreduction is defined as residual disease less than 1 cm in diameter, and preferably no visible residual disease. Studies have demonstrated that outcomes in advanced ovarian/fallopian tube cancer are the best in patients who have no residual disease.

Historically, most if not all patients with advanced stage ovarian or fallopian tube cancer underwent a PDS followed by chemotherapy. Several studies over the past decade have demonstrated that NACT followed by an interim debulking surgery after three to four cycles results in similar outcomes and less morbidity for advanced stage ovarian cancer.[63] This is particularly true for those advanced stage ovarian cancer patients who are either too ill and have significant surgical risks or for those in whom it appears that optimal debulking will not be feasible. Increasingly this practice paradigm is being adopted for patients with advanced ovarian/fallopian tube cancer and several clinical factors or laparoscopy can be used to predict the feasibility of achieving optimal (preferentially complete) surgical resection.

The surgical approach to ovarian/fallopian tube cytoreduction or debulking, either primary or interval, should involve an appropriate midline incision to provide adequate exposure for resection of all disease. Minimally invasive strategies for early stage ovarian cancer patients or for those undergoing interval debulking can be considered for select patients. The surgical goals of optimal cytoreduction are best accomplished in phases. For disease in the pelvis, surgeons must decide whether a total abdominal hysterectomy with bilateral salpingo-oophorectomy (procedure previously described) will suffice or whether an en bloc type of procedure that involves resection of a portion of the sigmoid colon and pelvic peritoneum will be required to remove all pelvic disease (Fig. 120.17). The latter is usually necessary when the cul-de-sac region and colon are extensively involved with disease. This resection generally involves a retroperitoneal approach with bilateral ureterolysis and careful dissection of the bladder. The colon is divided with a staple device proximal and distal to the areas of involvement, and an anastomosis with a staple device is generally quite feasible.

A second phase involves the upper abdomen. One key component of upper abdominal surgery includes resection of the involved portion of the gastrocolic and infracolic omentum. This generally involves resecting the omentum from the hepatic to splenic flexure, taking care to avoid injury to the stomach, transverse colon, spleen, pancreas, and liver. Disease along the inferior aspects of the diaphragm can be excised by dividing the falciform ligament, mobilizing the liver, and stripping the peritoneum off the diaphragm muscle fibers. Isolated nodules on the peritoneal surfaces can be resected or obliterated using a variety of techniques. On occasion, small bowel resection with anastomosis is required to achieve optimal cytoreduction.

A third phase involves removal of any obvious nodal metastasis. This generally involves adequate retroperitoneal exposure either in the pelvis or in the paraaortic region or both. Elective resection of nodes without clinical involvement in the setting of advanced ovarian cancer has been shown not to improve outcomes and should be avoided. The extent of initial disease and extent of resection should be documented in the operative report.

Transgender Care

The evolution of care for transgender patients has rapidly progressed over the last decade with an emphasis on the multidisciplinary team approach, including gynecologic surgeons.[67] Training in transgender surgical techniques remains lacking in many programs and approaches to care for patients is often limited to large quaternary care centers that have the subspecialists available.

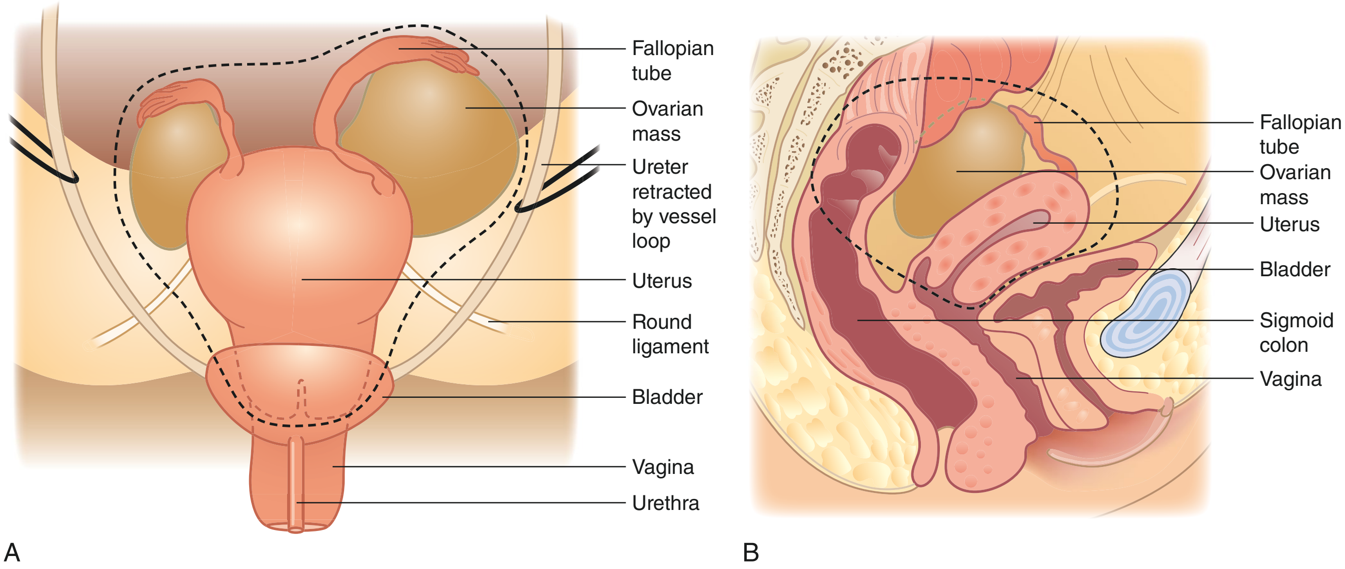

FIGURE 120.17 (A–B) En bloc cytoreduction of ovarian cancer in pelvis.

Surgical goals of care for female-to-male gender-affirming surgery include hysterectomy with bilateral salpingo-oophorectomy and vaginectomy followed by metoidioplasty or total phalloplasty, urethral lengthening, and scrotal reconstruction. Vaginal hysterectomy is preferred over laparoscopic hysterectomy due to the lack of visible abdominal scarring that contributes to stigma and lapse in body security and self-confidence while preserving the abdominal vasculature for future phalloplasty vascular needs.[68] However, surgical exposure may be limited in a nonparous patient and laparoscopic hysterectomy would be an acceptable safe alternative. Consultation with a fertility specialist is warranted before removal of the ovaries to discuss future conception options.

SUMMARY

It is important for the surgeon to be familiar with gynecologic conditions that affect patients throughout the spectrum of their lives and that often require surgical intervention. Knowledge of the relevant pelvic anatomy and the most common procedures should provide surgeons with the confidence to address gynecologic conditions in a skillful and compassionate manner.

UROLOGIC ANATOMY FOR THE GENERAL SURGEON

The organs of the genitourinary (GU) system span the entire retroperitoneum, pelvis, inguinal region, and genital region. Because of the close anatomic relationships of the organs in the abdomen and retroperitoneum, general surgeons must be familiar with all of the urologic organ systems to prevent iatrogenic injury and to deal with variations in normal anatomy. These challenges arise in many fields of surgery, including vascular, oncology, and colorectal surgery.

Upper Abdomen and Retroperitoneum

Adrenal

Beginning at the most superior aspect of the retroperitoneum lie the adrenal glands. These small, paired organs have two different embryologic origins and serve a primary endocrine function. The adrenal glands are composed of the cortex and medulla and are fused after development. The cortex is the outer layer of the adrenal gland and is derived from mesoderm.[1] On cross section, the layers, from external to internal, are the zona glomerulosa, zona fasciculata, and zona reticularis. The different zones secrete various steroid-derived hormones including mineralocorticoids (glomerulosa), glucocorticoids (fasciculata), and sex steroids (reticularis).[2] The adrenal medulla is derived from neural crest cells and is directly innervated by presynaptic sympathetic fibers.[1] The medulla is responsible for secreting catecholamines in response to sympathetic stimulation. The adrenal glands lie within Gerota fascia and have an orange-yellow appearance and an area of usually 3 to 5 cm in transverse diameter.[1] The arterial supply is through three sources: superior (inferior phrenic), medial (abdominal aorta), and inferior (ipsilateral renal artery). The venous drainage does not mirror the arterial supply; on the right, the single adrenal vein drains to the vena cava, whereas on the left, the adrenal vein drains into the left renal vein. Supernumerary veins can exist on either side because of anatomic variation. The adrenal glands are anatomically distinct from the kidney, although there are ventral and dorsal fascial investments that connect it to the kidney. The anatomic relations to the right adrenal gland are the vena cava on the anteromedial aspect and the liver and duodenum on the anterior aspect of portions of the adrenal gland. On the left, the pancreas and splenic vein are anterior to the cortical surface.

Kidney

The kidneys are the next paired organs just inferior to the adrenal glands. These organs are completely enveloped within the perirenal fascia (Gerota fascia) and are mobile structures supported only by the perirenal fat, renal pedicle vasculature, and abdominal muscles and viscera. Although Gerota fascia separates the kidney capsule and parenchyma from these adjacent organs and reduces the risk of renal injury with local dissection, renal parenchymal injury is possible with abnormal anatomy. The kidneys are approximately the size of a closed fist, measuring 10 to 12 cm in length and 5 to 7 cm in width. The right kidney typically lies slightly more inferiorly than the left kidney because of its position beneath the liver. Despite being located in the retroperitoneum, the kidney is well protected from external injury by the surrounding muscular and skeletal structures. Posteriorly, each kidney is covered by the diaphragm on the upper third of its surface and is crossed by the twelfth rib. The inferior aspect of the kidney is adjacent to the psoas muscle medially and the quadratus lumborum and transversus abdominis laterally.[1] The anterior surfaces of the kidneys are intimately related to several intraperitoneal structures. On the right, the liver is attached to the kidney by the hepatorenal ligament, and the anterior upper pole is adjacent to the peritoneal surface of the liver.[1] The duodenum lies on the medial aspect of the anterior right kidney, typically on the hilar structures. The hepatic flexure of the colon crosses anterior to the inferior pole of the right kidney. On the left, the superior pole of the kidney lies posterior to the tail of the pancreas and the splenic vessels and hilum. The spleen is situated anteromedial to the kidney and is directly attached to the kidney by the lienorenal ligament. The splenic flexure of the colon is draped over the caudal aspect of the anterior left kidney.

The renal vasculature has significant variability occurring in 25% to 40% of kidneys.[3] The typical vasculature is based on a paired artery and vein supplying the kidney as direct branches of the aorta and vena cava, respectively. The renal artery branches from the aorta inferior to the superior mesenteric artery at the level of the second lumbar vertebra. The renal artery then branches into four or five segments, each being an end artery.[3] The renal arteries are located posterior and slightly superior to the renal veins. The artery initially branches posteriorly into the posterior segmental artery. The anterior branches are variable but include the apical, upper, middle, and lower segmental arteries. These arteries branch multiple times within the cortical kidney, creating a complex filtration mechanism at the capillary level. The venous capillary branches coalesce to mirror the parenchymal arterial system. Renal segmental veins are not end vascular structures and collateralize extensively. The renal vein on the right is short, typically 2 to 4 cm in length, and enters the posterolateral inferior vena cava.[3] The left renal vein is longer, 6 to 10 cm, and travels anterior to the aorta and inferior to the superior mesenteric artery and enters the left lateral vena cava.[3] The left renal vein also is the common entry point for the left adrenal vein, gonadal vein, and a lumbar vein. Renal ectopia is accompanied by markedly variable and unpredictable renal vasculature, with multiple branches arising from the iliac arteries or aortic bifurcation.

Ureter

The upper collecting system begins within the renal parenchyma at the level of the papilla. The papillae coalesce to become the minor calyces, which, in turn, become the major calyces. The major calyces converge to form the renal pelvis. The ureter begins at the inferior aspect of the renal pelvis, where it narrows to become the ureteropelvic junction posterior to the renal artery.[2] Each ureter is typically 22 to 30 cm in length, depending on height, and courses through the retroperitoneum into the pelvis, where it connects to the urinary bladder at the ureterovesical junction.[4] At its origin, the ureter courses along the anterior psoas major muscle and is crossed by the gonadal vessels bilaterally. The ureters cross over the iliac vessels to enter the pelvis, just superior to the bifurcation of the iliac vessels into the internal and external segments. Once in the pelvis, the ureters course medially to enter the bladder. The ureters are divided into three segments (upper, middle, and lower) using this anatomic landmark as a junction point.[4] The upper segment runs from the ureteropelvic junction to the superior margin of the sacrum. The middle segment runs over the bony pelvis. The lower segment begins at the inferior margin of the sacrum and continues into the bladder. The ureteral lumen is not uniform throughout its length and has three distinct narrowing points: the ureteropelvic junction, crossing the iliac vessels, and the ureterovesical junction. The right and left ureters have separate anatomic relationships (peritoneal and retroperitoneal structures). On the right, the ureter is posterior to the ascending colon, cecum, and appendix. The left ureter is posterior to the descending and sigmoid colon. In the male, the ureters are crossed by the vasa deferentia as they emerge from the internal ring before turning medially to join the prostate. The ureteral blood is drawn from multiple vessels throughout its course and within the adventitia; the arterial vessels create an anastomosing plexus. In general, the upper ureteral segments have a medial vascular supply (i.e., renal artery and aorta), and the lower ureteral segments have a lateral vascular supply (i.e., internal iliac and various branches). This unique collateral blood flow allows extensive mobilization of the ureter, outside of its adventitia, without loss of its blood supply.[4]

The ureter is best identified, intraoperatively, in an area of normal anatomy and then followed to the area of concern. This is readily accomplished medial to the lower pole of the kidney or at the iliac bifurcation. After prior surgery or retroperitoneal disease processes, any of these rich collateral blood supply sources may not be contributory; thus, to minimize the risk of surgical devascularization, it is critical to avoid unnecessary extensive circumferential dissection of the ureter or dissection of the ureter in the subadventitial plane.

Pelvis

Bladder and Prostate

The bladder, the end reservoir for urine, is located within the inferior pelvis. The bladder, when empty, is located behind the pubic rami; but as the bladder becomes distended, the superior aspect of the bladder extends out of the pelvis and into the lower anterior abdomen.[5] The bladder can be injured on entering of the abdomen through a midline incision in the retropubic space (of Retzius) if the bladder is not displaced posteriorly when the midline rectus fascial incision is extended to the pubis. Superiorly, the bladder is covered by the parietal peritoneum of the pelvis as the peritoneum reflects off the anterior and lateral abdominal walls. The anterior and lateral bladder walls do not have a peritoneal surface but reside within pelvic fat and lie along the musculature of the pelvic sidewall or pubis anteriorly. Prior lower abdominal or pelvic surgery can change the anatomic relations of the bladder and cause it to be affixed abnormally within the pelvis. The bladder has a unique cross section with a urothelial lining creating a tight barrier from urine and a central muscular detrusor layer involved in the excretory function of the bladder.[6] Branches of the internal iliac artery, the superior and inferior vesical arteries, supply blood to the bladder. Similar to the ureter, the bladder has a rich collateral vascular network, so ligation or damage to an artery is not detrimental to the bladder. The innervation of the bladder is important because of the excretory function of the bladder. The bladder has autonomic and somatic innervation with a dense neural network to the brain. The sympathetic innervation to the bladder is through the hypogastric nerve, and the parasympathetic supply is through the sacral cord and pelvic nerve.[5] The anatomic relationships of the bladder differ between male and female patients. In the male patient, the posterior bladder wall is adjacent to the anterior sigmoid colon and rectum. Prior pelvic surgery, irradiation, or pelvic trauma can make the plane between these structures difficult to define, resulting in inadvertent injury. In the female patient, the parietal peritoneum becomes contiguous with the anterior uterus, and the superior bladder lies against the lower uterus, whereas the bladder base sits adjacent to the anterior vaginal wall. The spherical bladder funnels caudally into the bladder neck, and this becomes the tubular urethra inferiorly.

In the male patient, the first segment of the urethra is surrounded by and integrated into the prostate. The prostate, an endocrine gland involved with male reproductive function, is located immediately inferior to the bladder and invested in the circular fibers of the bladder neck. The prostate is surrounded by the lateral pelvic fascia on its anterior surface, by endopelvic fascia on its lateral surface, and by Denonvilliers fascia posteriorly.[7] The rectum sits immediately posterior to the prostate and is separated by a second layer of Denonvilliers fascia. This fascia also extends superiorly on the posterior prostate to encompass the seminal vesicles. The seminal vesicles are the reservoirs for seminal fluid, which makes up the majority of the ejaculatory fluid. The arterial supply to both structures is through branches of the inferior vesical artery. The venous drainage mirrors the arterial supply, draining through the inferior vesical veins and subsequently into the internal iliac veins. In addition to the rectum, the other major anatomic relationship of the prostate is the Santorini plexus, a network of veins derived from the dorsal venous complex of the penis.[7]

Urethra, Male Genitalia, and Perineum

The drainage of urine from the bladder is through the tubular urethra, which begins at the level of the bladder neck. In male patients, the urethra has five distinct segments: prostatic, membranous, penile, bulbar, and glandular (also known as the *fossa navicularis*). The prostatic and membranous urethra is surrounded by striated muscle, and when the urethra penetrates the GU diaphragm in the perineum, the outer layer becomes spongy, vascular tissue. Within the prostate, the ejaculatory duct opens into the urethra and serves as the exit point for seminal emission. The blood supply of the extraprostatic urethra is through the common penile artery, which is a branch of the internal pudendal artery.[5] The venous drainage of the urethra is through the circumflex penile veins and ultimately into the deep dorsal vein of the penis. The major surrounding structure in the proximal male urethra is the rectum, which sits posterior to the proximal bulbar segment. The female urethra is more regular in length and is approximately 4 cm long.[5] The female urethra contains three distinct layers as opposed to the male urethra. The proximal urethra is surrounded by smooth and striated musculature, which forms the urinary sphincter. The arterial and venous blood supply are through the internal pudendal, vaginal, and inferior vesical veins. The only structure adjacent to the female urethra is the anterior vaginal wall.

The male external genitalia consist of the penis, scrotum, and paired testes. The penis consists of three circular erectile bodies: the two dorsal corpora cavernosa and the ventral corpus spongiosum. The corpora cavernosa are responsible for penile erection; the corpus spongiosum provides support and structure to the urethra. Blood supply of the penis is through the external and internal pudendal arteries. The external pudendal artery supplies the penile skin; the internal pudendal artery supplies the urethra and the paired erectile bodies. The venous drainage of the penis is through the superficial and deep dorsal veins and the cavernosal veins. The penis is entirely an external structure, with all three erectile bodies terminating in the perineum. The scrotum is a surprisingly complex structure consisting of a muscular sac covered with a unique epidermal layer with no fat but many sebaceous and sweat glands. The sac is divided into two halves by a midline septum of dartos muscle. The blood supply to the scrotum is through the external pudendal arteries anteriorly and branches of perineal vessels posteriorly. Within the scrotum are the right and left testicles. The testicles have both endocrine and reproductive function in males. Typically, the testes are 4 to 5 cm long and 3 cm wide.[5] The vascular and genital ductal structures leave the testis from the mediastinum in the posterosuperior portion and travel through the scrotal neck into the inguinal canal. The spermatic cord is invested by the internal spermatic fascia, cremaster muscle, and external spermatic fascia, which are derived from the transversalis fascia, internal oblique, and external oblique, respectively. Arterial blood supply is primarily through the testicular or gonadal artery, which is a direct branch from the aorta inferior to the renal artery. Secondary blood supply to the testicle is through the cremasteric and vasal arteries. The venous drainage of the testicle initially begins as a pampiniform plexus coalescing into the gonadal or testicular veins. On the right, the vein drains directly into the vena cava; on the left, the vein drains into the left renal vein. The testicles are also responsible for spermatogenesis and for testosterone production. After production, the spermatozoa exit through a series of ductal structures that emerge into the rete testis, efferent ductules, epididymis, and ultimately the vas deferens. The epididymis is located posteriorly and slightly lateral to the testis. The spermatic artery, vein, and vas deferens are invested together in the fascial structures of the spermatic cord. The spermatic cord travels through the external inguinal ring through the inguinal canal and then into the pelvis through the internal inguinal ring. The spermatic cord is susceptible to injury during inguinal dissection for hernia repair, especially in redo cases, when it may be encased in fibrosis and injured without recognition. Significant injury to the spermatic cord may put the viability of the testis at risk, even though it is supported by three collateral arteries. The perineum is divided into an anterior and posterior triangle in the male by a line connecting the ischial tuberosities.[5] The posterior perineal triangle contains the anus and internal and external sphincters. The anterior triangle (or urogenital triangle) contains the corpus spongiosum and proximal aspect of the paired erectile bodies, the corpora cavernosa. The layers deepening toward the corpus spongiosum consist of the skin, subcutaneous fat, Colles fascia, and bulbospongiosus muscle (surrounding the corpus spongiosum) and ischiocavernosus muscles (surrounding the corpora cavernosa). The blood supply to this region is based on branches of the internal pudendal artery, and drainage is through the internal pudendal vein. The presence of a urethral catheter is helpful in palpating the location of the urethra, but the corpus spongiosum surrounding the bulbar urethra is still vulnerable to injury with dissection in an inflamed or obliterated anatomic plane.

ENDOSCOPIC UROLOGIC SURGERY

Urologists were early adopters of endoscopic surgery and began evaluating the urethra and bladder with cystoscopy in the early part of the 20th century. The first diagnostic and therapeutic endoscopic procedures were performed for treatment of urologic disease processes. Endoscopic procedures are divided based on intervention or evaluation of the lower or upper urinary tract as each has specialized procedure-specific equipment.

Cystoscopy, or cystourethroscopy as it is formally called, is used for evaluation of the urethra and the bladder. Cystoscopic procedures are typically performed to evaluate the lower urinary tract in the setting of hematuria, voiding symptoms, recurrent infections, or bladder outlet obstruction; for surveillance in the setting of malignant neoplasms; and for removal of GU foreign bodies and assessment of suspected trauma. Furthermore, cystoscopy can be used to perform diagnostic evaluation of the upper urinary tract with use of ureteral catheters and instillation of contrast material, which is visualized within the collecting system by fluoroscopy. Cystoscopy can be performed with both rigid and flexible endoscopes, each with certain benefits and advantages. Endoscopes are sized with the "French" (Fr) size system, which refers to the outer circumference of the instrument in millimeters. The rigid endoscope uses optical lens systems, similar to laparoscopes, and has excellent resolution. The inflexible structure is intuitive and easy to orient. Rigid cystoscopes have a range of sizes typically from 16 to 26 Fr; surgical endoscopes, or resectoscopes, have the largest size of 24 to 26 Fr.[8] Rigid endoscopes have a larger luminal diameter, which allows greater irrigation flow, improving visualization and passage of a number of working instruments. Rigid lower tract endoscopy is more difficult to perform in the awake patient, although it is much better tolerated in the female patient than in the male patient because of the short, straight urethra in the female patient. Flexible endoscopes are smaller, 15 or 16 Fr, and better tolerated by patients for examination. Both male and female patients can be examined with local anesthesia, usually consisting of lidocaine jelly instilled per urethra. The flexible endoscope does not require any specific patient positioning and can be used supine and at the bedside. Finally, because of the large deflection radius, the bladder is easily evaluated without changing the lens or patient position. The optics of flexible endoscopes continue to improve by advancements in camera chip capability, with new digital platforms approaching the resolution of optical lens systems. Pediatric endoscopes are smaller, 8 to 12 Fr, and are typically used in the operating room.

Upper tract evaluation is performed with either a ureteroscope or a nephroscope. The most common reason for either procedure is management of calculous disease, both ureteral and renal. Ureteroscopy can also be used to visualize and to inspect the upper collecting system, ureter, and renal pelvis; for hematuria originating from the upper urinary tract; for surveillance of urothelial carcinoma; and for treatment or biopsy of abnormal findings. Ureteroscopy is performed with both flexible and semirigid endoscopes, each with different benefits and purposes. Semirigid endoscopes are 6 to 7.5 Fr at the tip and gradually enlarge to 8 to 9.5 Fr.[8] The taper at the tip allows introduction into the ureteral orifice at the trigone of the bladder. These endoscopes have larger working channels that allow greater irrigation flow and a larger field of view. Because semirigid ureteroscopes are fairly inflexible, they are used to evaluate and to treat conditions below the level of iliac vessels and mid and distal ureter. Flexible ureteroscopes are 5.3 to 8.5 Fr at the tip and gradually enlarge to 8.4 to 10.1 Fr.[8] The major advantage of flexible ureteroscopes is the deflection of the tip, which ranges from 130 to 250 degrees in one direction and 160 to 275 degrees in the opposite direction, with newer endoscopes approaching 360-degree deflection. In addition, these endoscopes can be advanced through ureteral tortuosity and over external compression, such as the psoas muscle. The working channel on the flexible ureteroscope is typically smaller because of the fiberoptic system, and introduction of instruments, such as baskets or laser fibers, reduces irrigation flow. These flexible endoscopes can be used throughout the upper urinary tract but are particularly useful in the proximal ureter and renal pelvis and calyceal system.

The other method of upper tract endoscopy is through direct percutaneous access by puncture through the renal parenchyma into the renal collecting system. Percutaneous nephroscopy is most commonly used to treat large renal calculi. Management of upper tract urothelial tumors with fulguration and resection may also be performed via percutaneous nephroscopy. Nephroscopy may be performed with both rigid and flexible nephroscopes; however, most intervention is performed with the rigid system. The rigid nephroscope is placed through a percutaneous working access sheath, similar to a laparoscopic trocar, to visualize the stone or tumor. Rigid nephroscopes are usually 25 to 28 Fr, and their appearance is similar to a rigid cystoscope, although they have a fixed lens system rather than an exchangeable lens. There is also growing enthusiasm for "mini-perc" approaches, which involve smaller caliber instrumentation. Newer rigid nephroscopes are built on a digital platform that allows a larger working channel with comparable optics to a standard endoscope. Various intracorporeal lithotripters are placed through the working channel to fragment large stones into manageable pieces. Flexible nephroscopes are essentially flexible cystoscopes that are dual purposed for evaluation of the kidney. Flexible endoscopy of the upper tract is advantageous because all areas of the upper collecting system (upper, mid, and lower pole calyces) can be inspected regardless of angle or direction of the internal infundibula. At times, combined use of retrograde flexible ureteroscopy and percutaneous nephroscopy, in the prone patient under anesthesia, may be necessary to address complex renal anatomy for stone-related and other indications.

Numerous working elements are used in both upper and lower tract endoscopy. Guidewires are commonly used to access the upper urinary tract collecting system or the bladder and serve as guides to pass catheters, stents, and sheaths. Most guidewires have a flexible tip and a more rigid shaft and are constructed of an inner core and an outer covering, which may be hydrophilic or neutral (polytetrafluoroethylene). Guidewires range in size from 0.018 to 0.038 inch and have various lengths. Urethral catheters and ureteral catheters may be placed over wires to assist with direct placement into the lower or upper urinary system, respectively. Ureteral stents are hollow catheters with flexible ends that form a coil on the proximal and distal ends to maintain position within the collecting systems. Stents are placed to ensure drainage of the kidney and to bypass blockages of the ureter from inflammation, stones, or tumors. Many stents are composed of thermodynamic material, which becomes softer at higher body temperatures. Stents range in size from 4.8 to 10 Fr and have various lengths to accommodate variable ureteral lengths.

Ureteroscopic baskets are used to remove ureteral and renal calculi and to perform extraction and biopsy of tumors. These range in size from 1.3 to 3.2 Fr and are constructed of flexible material to allow placement into various calyceal locations within the kidney.

MINIMALLY INVASIVE ABDOMINAL AND PELVIC SURGERY

As opposed to traditional surgery with open incisions and self-retaining abdominal and pelvic retractors, urology has been a field of early adapters of minimally invasive approaches. The two large categories of minimally invasive approaches include laparoscopic and robotic-assisted laparoscopic procedures. Both of these can be performed for maladies of the GU tract in the retroperitoneum and pelvis. In the following sections we will review in general terms the surgical principles of both laparoscopic and robotic-assisted genital urinary surgery.

Laparoscopic

Laparoscopic surgery consists of insufflating the abdominal and pelvic cavity with carbon dioxide to create working space and then deploying straight instruments through 5- to 15-mm trocars to perform the intended procedure. Historically in urology laparoscopic surgery was used for numerous applications such as nephrectomy, partial nephrectomy, ureteral reconstructive procedures, prostatectomy (simple and radical), and even more complex oncologic resections of the bladder and retroperitoneal lymph nodes for testis cancer. However, modern-day urologic laparoscopic surgery is often more frequently used for nephrectomies, whereas the robotic-assisted laparoscopic surgery has supplanted pure laparoscopic techniques for most other procedures in the majority of centers in the United States.

Laparoscopic access can either be obtained through Verres needle or Hassan cutdown techniques, and each have their own pros and cons. The Verres needle is often faster but does have a slightly higher risk of small bowel injury. The Hassan cutdown technique is thus used in patients with previous abdominal surgeries or those at risk of adhesions, such as with previous radiation or altered anatomy. In addition, a laparoscopic Visiport can be used to obtain abdominal access. Once access is obtained, laparoscopic working ports are arrayed in a conformation to triangulate the organ of question, keeping a minimum of one hand width between ports to avoid clashing. Pneumoperitoneum pressures can range anywhere from 5 to 20 mm Hg to ensure insufflation. The assistant is used to orient the laparoscopic camera, which can be either a 0-degree lens or a 30-degree lens and angled around barriers. Common instruments that are advanced into these trocars consist of graspers, scissors (which often have cautery attachments for the tip of the instrument), suction irrigators, and bipolar energy devices. Using this combination of instruments, the exposure to the desired organ can be gained and the anatomy can be manipulated. Laparoscopic needle drivers and staplers are also available when suturing and or stapling is needed.

Robotic Surgery

Robotic assistance is an advancement in laparoscopy whereby the end of the laparoscopic instrument has an articulating wrist that is under the control of the surgeon. This adds significantly more degrees of freedom for the surgeon and thus enables more precise control of suture placement, knot tying, and fine dissection. The robotic procedures in general have a shorter learning curve than pure laparoscopic procedures due to these advantages, but they still share the same principles of pneumoperitoneum, gaining access safely and appropriate trocar placement. In addition, there is frequently an assistant at the bedside required for suctioning, irrigating, and instrument exchange as well as suture passage. Although there are many robotic systems in use around the world, Intuitive Surgical (Sunnyvale, California) has near complete market share within the United States, so we will focus on their system in this discussion.

Da Vinci Systems

Robotic surgery requires a console that is operated by a surgeon, which is a robotic tower consisting of four arms connected to a boom that is used to position the robot tower over the patient. The console consists of an enclosed system within which the surgeon operates using multiple pedals to control instruments, camera motion, and to toggle between arms. The console itself contains a viewing system that allows surgeons to have depth perception due to slightly offset camera lenses. The systems come in multiple formats, more commonly multiport, in which up to four robotic ports are able to be hooked up to the robotic console. In recent developments, a single-port robot is also being used, and in this configuration, there is a large trocar through which four instruments are advanced into the body cavity. Once inside the cavity, the instruments can spread out and be used to complete the procedure. There are pros and cons to the multiport and single-port robotic systems that are beyond the scope of this chapter.

Robotic Retroperitoneal Surgery

The most common indications are renal neoplasm, urothelial neoplasm, or upper urinary tract reconstruction. There are unique aspects of each of these indications, but in general, the principles of renal exposure are the same. Access to the kidney can be gained through transperitoneal ports or retroperitoneal ports. The transperitoneal approach is by far the most common and often consists of ports in a straight line at the level of the ipsilateral midclavicular line, which allows ports to be triangulated to reflect the colon and expose the kidney, the ureter, and the great vessels. The retroperitoneal approach relies on establishing a working space behind the colon when the patient is in flank position. There are numerous possible port configurations, but commonly, there will be ports placed below the eleventh rib and above the iliac crest. A balloon trocar is often used in this setting to establish working space behind the colon and around the kidney.

Robotic Pelvic Surgery

Robotic pelvic surgery is often performed for prostate cancer (radical prostatectomy), bladder cancer, benign prostatic hyperplasia (BPH), ureteral reconstruction, and gynecologic procedures. Exposure into the pelvis can be gained transperitoneally with horizontal ports above or below the level of the umbilicus, or extraperitoneally with a balloon port used to create working space. For these procedures, the patient is often in a Trendelenburg position, allowing the bowel to fall cephalad away from the operative field. The assistant port is often placed on the right side of the body to allow entry alongside the robotic ports.

UROLOGIC INFECTIOUS DISEASE

Urinary tract infections (UTIs) are a common medical problem, although patients with UTI referred to urologists for evaluation and treatment often have a complicated or unusual element to their diagnosis or management. Other infections treated by urologists include infections of the genital skin (a spectrum of disease from skin neoplasms, to cellulitis, to necrotizing fasciitis) and reproduction organs in males (i.e., orchitis, epididymitis, or prostatitis). Furthermore, these infections may require simple antibiotic therapy, multimodal treatment with surgical drainage, or debridement and management in an intensive care setting. Urinary tract obstruction with proximal infection may result in sepsis, challenging the skills of the urologist and surgical critical care specialist.

Uncomplicated Urinary Tract Infection

Recent literature indicates that UTIs in adult females and males accounted for 39 million office visits and 6 million emergency department visits.[9] In adult patients, more than 50% of females and 12% of males will develop a UTI during their lifetime.[9] Urinary infection is considered "uncomplicated" when it occurs in the immunocompetent host, without underlying anatomic or physiologic abnormalities of the urinary tract in females. UTI diagnosed in males is generally considered "complicated." For diagnosis of a UTI, a clean catch, midstream urine specimen is preferred, and on culture, 105 colony-forming units must be demonstrated. In catheterized specimens, UTI can be diagnosed with as little as 103 colony-forming units. The typical symptoms associated with UTI are dysuria, frequency, urgency to void, and malodorous urine. Because of the inherent differences in etiology, evaluation, and treatment, uncomplicated UTIs are divided into those occurring in premenopausal and postmenopausal females. A third category of uncomplicated UTI, that occurring in pregnant patients, is beyond the scope of this overview. In general, risk factors include genetic, biologic, and behavioral; specific aspects are discussed with each group.

Premenopausal Patients

History and physical examination of patients in this age group presenting with symptoms of UTI are particularly important because of overlapping disease processes. In patients without vaginal discharge, the majority can be expected to have a UTI as the diagnosis. However, in sexually active females, sexually transmitted infections (STIs) must be considered, especially in the setting of a negative urine culture. Furthermore, in patients with vaginal discharge, vaginitis caused by yeast, trichomoniasis, and bacterial vaginosis are possible causes. Risk factors for UTI in this population of patients include frequent sexual intercourse, initial UTI at a young age, maternal history of UTI, and number of pregnancies and deliveries.[10] Important aspects of the physical examination in these patients include palpation of costovertebral tenderness (assessing for ascending infection) and pelvic examination to evaluate for STI. The most common cause of infection in these patients is *Escherichia coli* (80%–85%), followed by *Staphylococcus saprophyticus* (10%–15%) and *Klebsiella pneumoniae* and *Proteus mirabilis* (4% each).[10] Empirical therapy is acceptable, although confirmatory urine cultures are useful as the incidence of antibiotic resistance continues to rise. Prevention includes increased hydration and evaluation of hygiene practices.

Postmenopausal Patients

As in younger patients, history and physical examination are important aspects of UTI evaluation in this group of patients. Presenting symptoms are similar in this group, although some elderly patients may simply present with altered mental status. Furthermore, an important component in diagnosis and treatment of postmenopausal females is the change in the vaginal pH levels and change or reduction in lactobacillus in the vaginal flora. The physical examination findings may differ in these patients as STIs are less likely but physical changes, such as pelvic organ prolapse and incomplete bladder emptying, become causative factors. In addition, the pathologic bacterial species are different. *E. coli* continues to be the predominant organism, but in this age group *P. mirabilis, K. pneumoniae,* and *Enterobacter* species become more prevalent pathogens.[10] Again, empirical therapy is acceptable, but urine cultures are important because of increasing antibiotic resistance patterns and differing organisms. Prevention includes increased hydration and evaluation of hygiene practices.

Complicated Urinary Tract Infection

Complicated UTIs require more vigilance on the part of the treating physician because of patient factors that may lead to a more rapid progression or worsening of the infection. By definition complicated UTIs occur in males and in patients with diabetes, immunosuppression, upper tract infection, resistant organisms, urinary tract anatomic abnormalities, prior surgery, calculous disease, spinal cord injury, or recent or current indwelling Foley catheter. Essentially, any abnormality of physiology or anatomy that is etiologic in a UTI or a UTI that occurs in such a setting or in the immunocompromised patient is considered complicated. In these patients, similar evaluation is warranted, but the evaluation should not be limited to simply history and physical examination. Empirical treatment of complicated UTI alone is not optimal, and urine cultures should be performed on all patients with suspected complicated UTI before initiation of antibiotic therapy, whenever possible. In addition, imaging is indicated in these patients because of concern for calculous disease and urinary stasis, so at a minimum, simple radiography of the kidneys, ureters, and bladder (KUB study) and renal ultrasound, and potentially further assessment with cross-sectional radiographic imaging, should be performed in patients with equivocal or concerning findings. Finally, antibiotic therapy alone may not be adequate, and these patients may require surgical drainage of obstructed urinary systems or later surgical correction of anatomic abnormalities or removal of urinary stones (once infections are treated) to prevent recurrent UTIs. Consultation with infectious disease specialists may also be indicated in patients with urologic anatomic abnormalities and recurrent UTIs with resistant organisms.

Urinary Tract Infection in Males

Because of the lower incidence of UTI in males, when they present with symptoms of infection, it is always considered complicated, regardless of other patient factors. As in females, younger males (younger than 50 years) and older males (older than 50 years) have different causes of their UTI and symptoms. Common presenting symptoms are urethritis, dysuria, hesitancy, frequency, and urgency of urination. A history and physical examination in these patients are important to delineate different sources of symptoms or UTI. Males can present with these symptoms and have different diagnoses, including UTI, STI, urethritis, and chronic pelvic pain. Furthermore, bacterial infections can extend to other proximal areas of the GU system, such as the prostate and testicle. Males younger than 50 years are more likely to have STI as the cause rather than UTI. These males should have a thorough sexual history, genital examination, and microscopic urinalysis performed. Urethral swab or urine tests for STI should be performed as well. Males older than 50 years often have underlying lower urinary tract symptoms (LUTS), and this can be a contributing factor. Males in this age group more frequently will have UTI as a source of their symptoms, and common urinary pathogens, as in females, should be considered. Furthermore, older males should be questioned about recent surgical procedures, catheterization, or hospitalization. Elderly patients can also present with mental status or behavioral changes as their only symptom of UTI, and this diagnosis must be considered in these patients. A lower threshold for imaging and hospital admission is necessary in males with UTI as they may present with more systemic symptoms. Patients who cannot tolerate oral intake, are immunocompromised, or have medical comorbidities should be admitted with cross-sectional imaging performed. Broad-spectrum intravenous antibiotics, based on local resistance patterns, and fluid resuscitation should be initiated in these patients while the initial workup and evaluation are completed. Urinary obstruction or stone disease in these patients constitutes a urologic emergency and must be addressed rapidly.

Specific Complicated Genitourinary Infectious States

Pyelonephritis

Pyelonephritis is a spectrum of infectious or inflammatory processes that involve the kidney collecting system or parenchyma. Pyelonephritis results from a UTI moving proximally upward from the lower urinary tract. In the simple form, pyelonephritis may be treated on an outpatient basis with oral antibiotics for 1 to 2 weeks. In this group of patients, urine culture is necessary to identify the causative organism. If the patient appears more acutely infected, hospitalization may be warranted for broad-spectrum intravenous antibiotic therapy, fluid resuscitation, and cross-sectional imaging. Emphysematous pyelonephritis represents an advanced form of pyelonephritis and is considered a urologic emergency. Often occurring in the diabetic patient, these uncommon infections demonstrate a significant necrotizing infection of the kidney with gas-forming organisms (typically *E. coli* in a facultative anaerobic metabolic state) with pockets of gas within the parenchyma apparent on imaging (Fig. 121.1). The common bacterial pathogens include *E. coli, P. mirabilis,* and *K. pneumoniae.*[11] These patients require either prompt percutaneous drainage of the infection or rapid nephrectomy. Most patients who present with this condition are diabetic or have significant medical comorbidities, and control of the metabolic abnormalities, aggressive broad-spectrum antibiotic therapy, and supportive critical care are essential. Xanthogranulomatous pyelonephritis is a chronic infectious process resulting from renal obstruction, recurrent infection, and renal calculous disease. The disease presents in three forms (focal, segmental, or diffuse), and each is treated in a different manner. The underlying histologic process involves a foamy, lipid-laden, macrophage infiltrate in the renal parenchyma with extensive inflammation, fibrosis, and loss of renal function. On imaging, there may be indications of collecting system dilation; however, drainage attempts often are unproductive because the material is often solid or too viscous to drain. Patients with focal or segmental disease may be treated with antibiotics, but those with diffuse disease frequently require nephrectomy. The risk of iatrogenic adjacent organ injury is high in these nephrectomies, and the renal hilum may be so inflamed and fibrotic that the renal

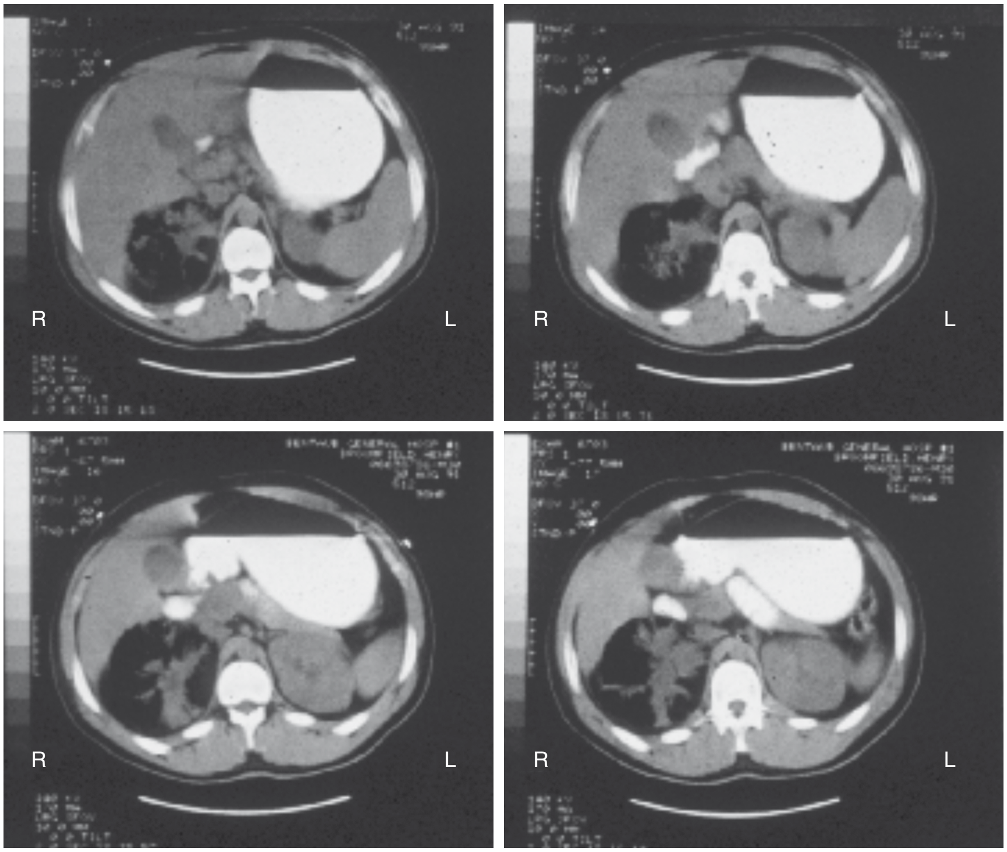

FIGURE 121.1 Emphysematous pyelonephritis. This CT scan demonstrates extensive destruction of the right kidney with intraparenchymal gas on the right, obliterating the renal architecture. The left kidney is normal.

vessels cannot be individually dissected. These cases may require placement of a vascular pedicle clamp with renal excision and oversewing of the pedicle.

Male Genital Organ Infection

UTIs may ascend into the genital ducts, resulting in infection of the prostate, epididymis, or testicle. Beginning in the urethra, the verumontanum is the exit point of the seminal vesicles and vas deferens into the urinary tract. Prostatitis refers to any inflammatory process affecting the prostate, but the general surgeon more commonly may encounter acute bacterial prostatitis, which results from bacterial infiltration into the prostatic parenchyma. Most infections of the prostate are secondary to gram-negative bacterial infection and typically are associated with UTI. Two important considerations in these patients are physical examination and disease extent. Although a full history and physical examination are warranted, elimination of digital rectal examination (DRE) should be considered as pressure exerted on an infected prostate may lead to hematogenous spread of the bacteria. In addition, patients who do not have reasonably rapid resolution of their symptoms should be evaluated for prostatic abscess. Prostatic abscesses typically do not respond to antibiotic therapy and require transurethral unroofing or percutaneous drain to allow adequate drainage.

Epididymitis-orchitis results when the UTI ascends through the vas deferens into the epididymis or testicle. Again, the cause is different according to the patient's age; males younger than 35 years typically have an STI as a source, commonly *Chlamydia trachomatis,* whereas males older than 35 years will often have infections related to *E. coli.* Examination of these patients is often difficult because of significant swelling of the affected epididymis or testicle; scrotal ultrasound is useful diagnostically, especially to rule out associated abscess. When infection is advanced, the entire ipsilateral scrotal contents become involved, with overlying skin fixation and edema. It may be difficult to distinguish this entity from late torsion, incarcerated inguinal hernia, or testicular tumor with necrosis and inflammation. Patients without abscess may be managed with antibiotic therapy, rest, and scrotal elevation; however, recovery is slow, with eventual resolution of edema and discomfort. If abscess is present, surgical drainage and often orchiectomy are indicated. A subset of patients may have persistent pain or mass, and on repeated Doppler imaging, signs of testicular ischemia or persistent inflammation may be noted. These patients require exploration and possible orchiectomy to resolve the process.

Fournier Gangrene

Fournier gangrene is a necrotizing infection of the male genital and perineal skin and subcutaneous tissues, similar to other progressive fasciitis and necrotizing soft tissue infections (Fig. 121.2). When the genitalia are involved, patients typically present with significant pain and tenderness, scrotal and genital swelling, discoloration or frank necrosis, crepitus, and, at times, foul-smelling discharge. Fournier gangrene is usually a polymicrobial infection with microaerobes, anaerobes, and gram-positive and gram-negative organisms.[12] Risk factors for development include peripheral vascular disease, diabetes mellitus, malnutrition, alcoholism, and other immunocompromised states. This disease represents a urologic emergency. Treatment requires urgent surgical drainage with aggressive debridement of the necrotic tissue, broad-spectrum intravenous antibiotics, and intensive monitoring with supportive care. The magnitude of the debridement depends entirely on the degree of progression of the process. It is rare for the process to involve the testicles or deep tissues of the penis deep to the tunica vaginalis and Buck fascia, respectively, so these structures should be preserved. It is uncommon for the urethra to be involved,

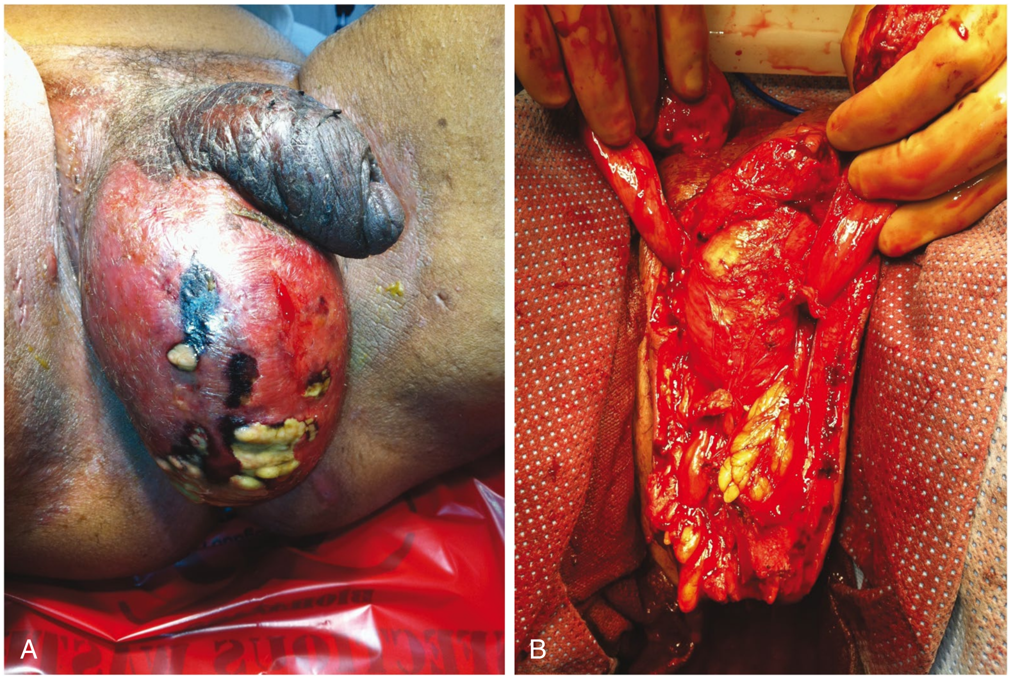

FIGURE 121.2 Fournier gangrene. (A) Skin necrosis, purulence, and edema of the scrotum. The skin can also appear normal, with much more subtle physical findings in some cases. (B) Appearance after extensive debridement of scrotal skin and underlying tissues. The base of the penis is visible centrally; the testes are elevated out of the field, and the spermatic cords are visible anteriorly.

although a defined urinary tract source may be evident, such as a urethral stricture, with perforation and local infection. Suprapubic tube diversion is generally not necessary initially; urethral catheter drainage is generally sufficient. Once the active infection is controlled, the predominant management issues become wound care and reconstruction, which may require delayed skin grafting for tissue coverage.

Atypical Urinary Tract Infections

Fungal Infection

Fungal infections in the urinary system are most common in specific populations of patients: diabetics, immunocompromised patients, and the elderly. Fungal infections may not be symptomatic and, in an outpatient setting, may not require therapy. Most fungal infections are related to the *Candida* species, and it is incumbent on the treating physician to determine which infections require treatment and which represent contamination. Patients who require careful evaluation and treatment include neutropenic patients and intensive care patients, who may need evaluation for an internal source such as a fungus deposit (ball) in the bladder or kidney. Infectious disease consultation is valuable in these cases because the organisms are atypical and selection of treatment agents may not be straightforward. Renal and bladder imaging with ultrasound may demonstrate a treatable source. These patients may need antifungal bladder or kidney irrigation or occasionally endoscopic removal.

Tuberculosis

The GU tract is the third most common extrapulmonary site for tuberculosis infection. This disease is spread hematogenously from the lungs and into the affected organ system. Most patients with GU tuberculosis are immunocompromised, so assessment of HIV infection status is important. Patients present with various symptoms that include voiding symptoms, sterile pyuria or hematuria, and chronic kidney disease. Not all patients will have a positive purified protein derivative (PPD) test result, and diagnosis is confirmed with acid-fast bacilli smears of urine and mycobacterial culture with sterile pyuria, chest radiograph, and imaging of the GU system to look for anatomic abnormalities. Tuberculosis affecting the kidney may result in segmental or global glomerular dysfunction, and progression antegrade down the urinary system may result in ureteral strictures. Tuberculosis of the epididymis may result in chronic epididymitis or mass. Antibiotic therapy consists of 2 months of a four-drug regimen with a subsequent 7-month treatment with isoniazid and rifampin. Infectious disease consultation is mandatory in treating these patients because of public health concerns. Significant anatomic infection or functional change or loss may ultimately require surgical excision.

Parasitic Infection

With the ease of global transportation and a mobile global population, parasitic infections are considerations in patients with recent travel histories. The main parasitic infections of the GU system are schistosomiasis, echinococcal infection, and filariasis. Each parasite has a different point of entry, systemic spread, and organ infestation. Typically, in schistosomiasis, the parasite enters the body percutaneously and spreads through the venous and lymphatic system. Most infestations affect the bladder, resulting in chronic inflammation and granulomas. These patients present with LUTS or hematuria. Medical therapy (praziquantel) can be used to treat granulomatous disease; however, untreated infections can result in squamous cell carcinoma of the bladder. Echinococcal infections are spread through ingestion of contaminated food, and the parasite penetrates the intestinal walls and infests the liver. On occasion, renal infestation can occur, with the parasite becoming encysted in the parenchyma. Medical therapy can shrink the cysts, but surgical removal by partial or total nephrectomy is required for cure. These cysts must be removed intact as rupture or spillage of internal contents can result in severe anaphylaxis. Filariasis results from direct infection of the lymphatic system through percutaneous entry. The parasite creates noticeable symptoms when it dies, resulting in obstruction of the lymphatics. Only mild infestation can be treated with oral therapy (albendazole); advanced disease requires excision and reconstruction.

VOIDING DYSFUNCTION, NEUROGENIC BLADDER, INCONTINENCE, AND BENIGN PROSTATIC HYPERPLASIA

A central aspect of urology is management of bladder function and evaluation and treatment of bladder dysfunction. The bladder is a large muscular sac responsible for storing and eliminating urine. Common dysfunctions of the bladder include neurogenic problems with bladder function, storage problems, incontinence, and outflow issues related to BPH or enlargement. Changes in these functional areas are one of the most common reasons for urologic consultation. Although this is a broad area of urology, concentrating on these core divisions will give the general surgeon an understanding of the complex dynamics of bladder function and dysfunction.

Neurogenic Bladder

Patients with neurogenic bladder dysfunction present with a wide spectrum of neurologic diseases or injuries that affect bladder function on the basis of the location of the injury or disease process. There is a complex interaction between the bladder and brain that primarily regulates bladder storage and bladder emptying. Bladder storage is driven by the sympathetic nervous system, specifically at the level of the adrenergic receptor. α-Adrenergic receptors are the most common adrenergic receptors in the bladder, prostate, and urethra; most are α_1 and α_2, with three subtypes of α_1 identified: α_{1a}, α_{1b}, and α_{1d}.[13] The α_1 receptor is the most common subtype in the lower urinary system. Bladder emptying is driven by the parasympathetic stimulation of cholinergic receptors, specifically the muscarinic receptors. The predominant muscarinic receptors in the bladder are M2 and M3.[13] Sensory information is carried away from the bladder by myelinated and unmyelinated afferent nerve fibers traveling through the pelvic and pudendal nerves. Any interruption in the sympathetic or parasympathetic nervous system and its communication with the bladder can result in neurogenic dysfunction. In addition, several centers within the pons, midbrain, and cerebral cortex have direct effect on the storage and emptying of the bladder.[13] Voiding is initiated at the level of the pontine micturition center, which sends out a parasympathetic signal to the bladder to initiate voiding. The pontine micturition center is inhibited by the periaqueductal gray located in the midbrain, and this is connected to the afferent signaling pathways from the bladder. Based on this standard sensory function, specific voiding symptoms or LUTS can be predicted by the location of neurologic disease or injury.

Basic evaluation of these patients includes a through history with neurologic and urologic historical focus, physical examination (focusing on the abdomen, pelvis, and peripheral and central nervous system), and urinalysis. Additional evaluation is tailored to location of injury. Cortical brain disease and injury, such as cerebrovascular accident, are evaluated by history, physical examination, and urinalysis. These disease processes do not directly affect the bladder function, and patients are treated on the basis of symptoms alone. Spinal cord lesions are divided into suprasacral spinal lesions (spinal cord injury, infarcts) and sacral or peripheral spinal cord lesions (pelvic plexus damage from surgery, diabetic neuropathy). Patients with lesions of the suprasacral spinal cord tend to have increased bladder muscle tension, which results in abnormal elasticity of the bladder (poor bladder compliance).[14] In addition, these patients have incoordination of the bladder and urinary sphincter, resulting in detrusor-sphincter dyssynergia. Patients with sacral or peripheral nerve lesions tend to have variable LUTS but typically do not have changes in bladder elasticity.[14] The detrusor muscle is often partially or completely nonfunctional, and the urinary sphincter remains closed. Specialized evaluation of the patients with spinal cord lesions includes upper tract ultrasonography to monitor for evidence of hydronephrosis and urodynamic evaluation. Urodynamic evaluation involves measuring the elasticity of the bladder on filling (compliance), the pressure generated on emptying (detrusor function) by recording the abdominal pressure, and the intraluminal bladder pressure with specialized catheters. Surveillance cystoscopy is indicated in chronic patients to rule out the development of intravesical disease. Treatment for neurogenic bladder has recently been revolutionized by the introduction of onabotulinum toxin. In the past, these patients required complex regimens of antimuscarinic agents and reconstructive surgery. Now, with the use of onabotulinum toxin, most patients are treated with periodic cystoscopic injections and intermittent catheterization.

Problems With Bladder Storage Symptoms and Abnormalities

Overactive bladder (OAB) is the most common storage-related problem of the bladder. It is defined as urinary urgency with or without urgency urinary incontinence in the absence of UTI or other obvious disease.[15] Typical symptoms of this problem include urgency, urinary frequency, nocturia, and urgency urinary incontinence. Urgency refers to the sudden, compelling desire to pass urine that is difficult to defer and replaces the normal urge.[15] Urinary frequency is the complaint of micturition occurring more frequently than previously deemed normal and characterized by daytime and nocturnal voids.[15] Nocturia is the complaint of interruption of sleep one or more times because of the need to urinate.[15] Finally, urgency urinary incontinence is the involuntary loss of urine associated with urgency.[15] A difficult aspect of this disease process is that it occurs in the spectrum of other LUTS and may be the result of long-term bladder outflow obstruction. Other conditions to consider in patients who present with OAB and LUTS are UTI, urinary calculi, diabetes, polydipsia, neurogenic bladder, and malignant disease. OAB has a worldwide prevalence of 11%, and with the aging population, this is presumed to increase over time.[16]

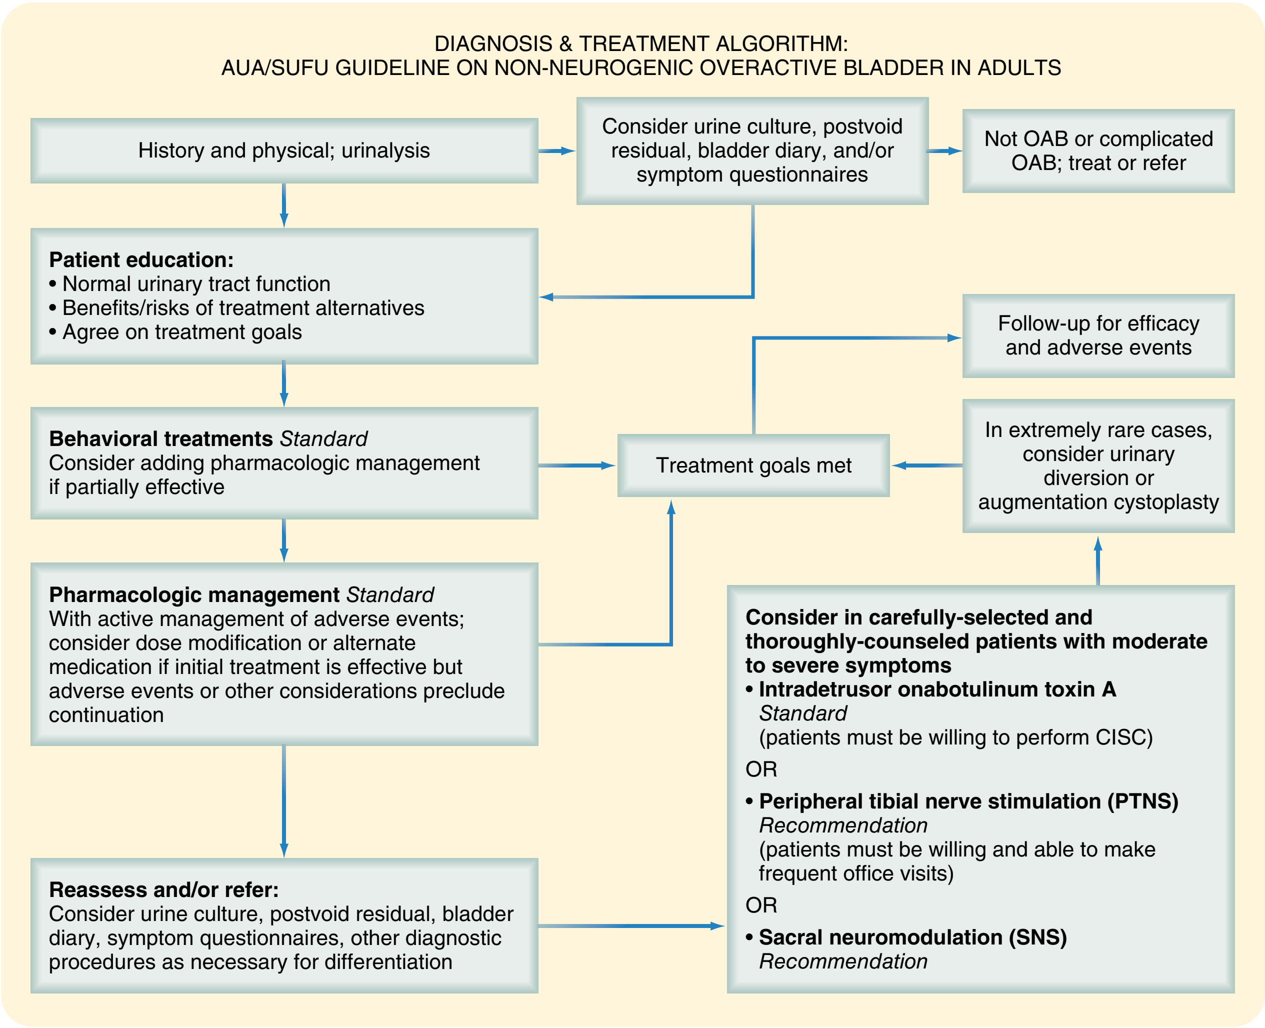
All patients who present with OAB should undergo a thorough evaluation. At the basic level, this includes a thorough history to fully disclose the symptoms and to rule out other causes. Historical elements that may be contributory include caffeine intake, constipation, recurrent UTI, pelvic organ prolapse in females and prostatic enlargement in males, and excessive fluid intake. Physical examination should be directed toward evaluation of the abdomen, pelvis, and neurologic systems. Other findings may include decreased mental status or cognitive function and peripheral edema. The last absolute examination element is urinalysis, which can reveal infection, inflammation, or hematuria that may indicate more serious disease. Simple adjunctive tests that can be performed in the office include measurement of postvoid residual urine volume, noninvasive flow test, validated symptom questionnaires, and voiding diaries. Specialized tests and evaluation performed by the urologist may include cystoscopy, ultrasound, and urodynamic testing as appropriate. However, current guidelines do not require any of these specialized tests for initiation of treatment.[17]

Treatment of OAB is directed toward therapy, symptoms, and motivation of the individual patient (Fig. 121.3). As many patients suffering from this problem take multiple medications, pharmacologic therapy is not always offered as an initial treatment. Behavioral therapies are the first-line treatment for all patients. Behavioral therapies may include lifestyle modifications or specific physical therapies. Typically, this includes fluid intake management and modification with particular attention paid to timing of fluid intake and amounts. For example, in patients who complain of nocturia, limiting nighttime fluid intake can be beneficial. Bladder training is a noninvasive method of physical therapy whereby the patient postpones voiding to lengthen the time intervals between voids. This may be coupled with urgency suppression and timed voids to reinforce retraining of the sensory output from the bladder. Finally, voiding diaries are important to help the patient and urologist quantify the number of voids and voided amount to better target improvement goals and to tailor therapy. Pharmacologic management continues to be a mainstay of treatment and is indicated for patients as an adjunct to behavior therapies or for patients unresponsive to first-line therapy. Classic pharmacologic therapy is antimuscarinic agents that target the parasympathetic muscarinic cholinergic receptors, primarily M2 and M3, and block the action of these receptors. Most of the drugs in this category are administered daily and have the common side effects of dry mouth, dry eyes, and constipation. A newer pharmacologic agent, beta agonists (β_3), targets receptors in the detrusor muscle to stimulate bladder relaxation. Treatment options for patients who fail to respond to these therapies fall into the specialized third-line treatments, which include neuromodulation (either peripheral or central), onabotulinum toxin, chronic indwelling catheters, and augmentation cystoplasty.

Urinary Incontinence

Urinary incontinence is the involuntary loss of urine; it can be divided into stress urinary incontinence (SUI), urge urinary incontinence, and mixed urinary incontinence.[15] "Overflow incontinence" is another form of incontinence, which is often considered as an etiologically separate entity. National data indicate that the prevalence of urinary incontinence in America is 49.6% in females older than 20 years.[18] Males are typically affected after the age of 50 years, and incontinence develops as a symptom of LUTS or other problems rather than as a primary complaint as in females. SUI is defined as the involuntary loss of urine with Valsalva maneuver.[15] Urge urinary incontinence is the involuntary loss of urine associated with a strong urge to void.[15] Mixed urinary incontinence is any combination of these two causes.

Evaluation of these patients includes history, physical examination (including pelvic examination), urinalysis, postvoid residual



DIAGNOSIS & TREATMENT ALGORITHM:
AUA/SUFU GUIDELINE ON NON-NEUROGENIC OVERACTIVE BLADDER IN ADULTS
History and physical; urinalysis
Consider urine culture, postvoid residual, bladder diary, and/or symptom questionnaires
Not OAB or complicated OAB; treat or refer
Patient education:
• Normal urinary tract function
• Benefits/risks of treatment alternatives
• Agree on treatment goals
Follow-up for efficacy and adverse events
Behavioral treatments Standard
Consider adding pharmacologic management if partially effective
Treatment goals met
In extremely rare cases, consider urinary diversion or augmentation cystoplasty
Pharmacologic management Standard
With active management of adverse events; consider dose modification or alternate medication if initial treatment is effective but adverse events or other considerations preclude continuation
Consider in carefully-selected and thoroughly-counseled patients with moderate to severe symptoms
• Intradetrusor onabotulinum toxin A
Standard
(patients must be willing to perform CISC)
OR
• Peripheral tibial nerve stimulation (PTNS)
Recommendation
(patients must be willing and able to make frequent office visits)
OR
• Sacral neuromodulation (SNS)
Recommendation
Reassess and/or refer:
Consider urine culture, postvoid residual, bladder diary, symptom questionnaires, other diagnostic procedures as necessary for differentiation

FIGURE 121.3 Algorithm for diagnosis and management of overactive bladder *(OAB). AUA,* American Urological Association; *CISC,* clean intermittent self-catheterization; *SUFU,* Society of Urodynamics, Female Pelvic Medicine & Urogenital Reconstruction. (Adapted from Lightner DJ, Gomelsky A, Souter L, et al: Diagnosis and treatment of overactive bladder [non-neurogenic] in adults: AUA/SUFU Guideline amendment 2019. *J Urol.* 2019;202:558.)

volume measurement, and voiding diaries. The history and physical examination are important to rule out any complicating factors including neurogenic source, anatomic changes (pelvic organ prolapse in the female patient and prostatic enlargement in the male patient), and prior surgical intervention (radical prostatectomy in the male patient or hysterectomy in the female patient) that might affect evaluation and the treatment decision. In the neurologically normal patient with no confounding factors, nonsurgical management is the first step in treatment before any surgical intervention. As with OAB, behavior modification and bladder training are the initial steps. Dietary modification is important for management of urinary incontinence. Patients are counseled to limit fluid intake to around 2 L/day, depending on body size and activity level. In addition, patients should limit caffeine intake and other bladder irritants including alcohol, carbonated beverages, spicy foods, and citrus juices and fruits. Furthermore, bowel programs should be initiated to ensure that the patient has normal bowel function and is not constipated. Other nonsurgical treatment includes weight loss to a normal body mass index (BMI) and exercise, particularly core muscle exercises. Pelvic floor muscle training and biofeedback have been shown to have acceptable rates in helping patients achieve satisfactory management of their urinary incontinence.

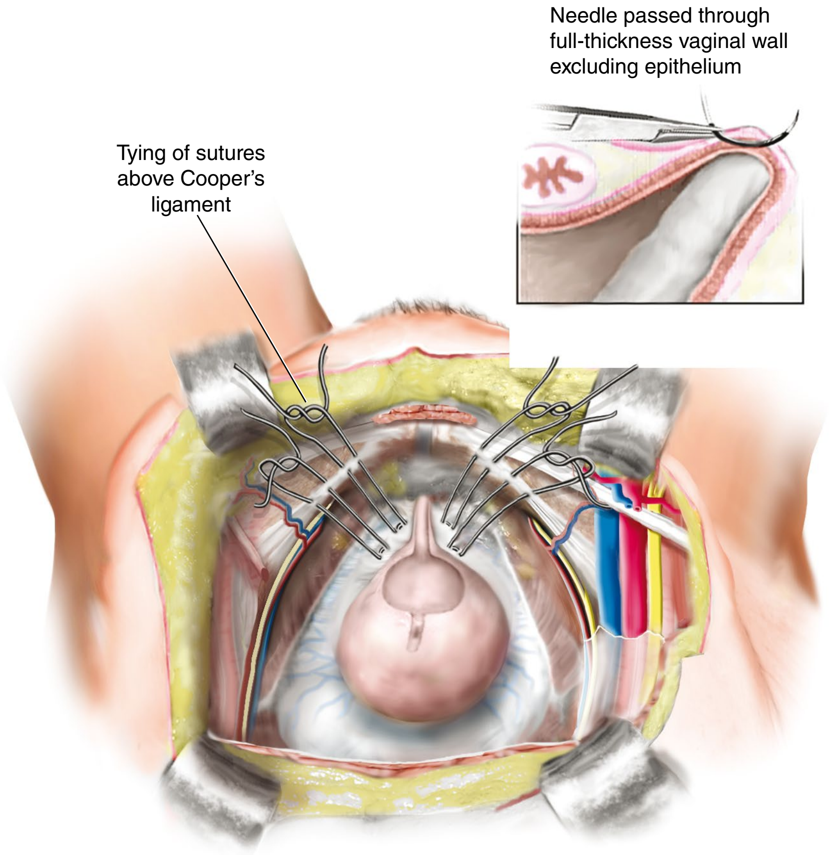
Female

Stress urinary incontinence. Surgical treatment options for females and males differ because of the inherent mechanism causing the incontinence, typically poor pelvic anatomic support in females and sphincteric in males. In females, treatment options progress from less to more invasive. The simplest treatment is injection of a urethral bulking agent through a cystoscopy. The objective of this treatment is to improve coaptation of the urinary sphincter and to increase the urethral wall volume. Unfortunately, this treatment is not likely to produce long-term cure, and retreatment or progression to other options is often necessary. The next option is placement of a midurethral sling to resupport the central hammock of the urethra and to provide backing to the urethra during stress maneuvers. The midurethral sling can be performed using a retropubic, transobturator, or single incision technique, with a passage of a small, thin piece of mesh between the urethra and anterior vaginal wall. These approaches have a higher success rate, and long-term data show cure rates of approximately 90%.[19] With the success and ease of the midurethral sling, fewer open retropubic Burch colposuspensions are performed for primary treatment of female SUI. These procedures also work to improve the support of the urethra and to reduce urethral hypermobility. Mesh should not be used for female SUI surgery when there is noted urethral perforation during the procedure, or when other concomitant urethral procedures, such as diverticulectomy, are needed. In addition, many surgeons avoid mesh when there is poor tissue quality, risk factors for poor wound healing such as radiation, or significant scarring from previous procedures. On the other hand, when mesh is less desirable, an autologous pubovaginal sling can be performed with harvested abdominal fascia and is passed more proximally behind the urethra toward the bladder neck. In cases of recurrent SUI, previous mesh erosion, concomitant abdominopelvic surgery (such as for prolapse), or a patient desire to avoid mesh/graft, the Burch colposuspension remains an option that can be performed open, laparoscopically, or robotically. In this procedure (Fig. 121.4), paravaginal and paraurethral connective tissue is sutured to Cooper's ligament on the anterior pubic ramus. This reduces urethral hypermobility by providing anterior support to the surrounding tissues and partially fixing the urethra anteriorly toward the pubis. Given the proximity of the urethra and bladder, most surgeons perform a cystoscopy intraoperatively to ensure no injury has occurred during most SUI procedures.

Prolapse

A unique anatomic circumstance of female urinary incontinence is the ability of organs to prolapse through the vagina and cause or exacerbate the underlying urinary symptoms. Risk factors for female pelvic organ prolapse include increasing age, multiparity, prior hysterectomy, elevated BMI, and chronic cough. Thus, in a female patient with symptoms suggestive of SUI, mixed incontinence, or a pelvic bulge a pelvic exam is necessary. The pelvic organ prolapse questionnaire (POP-Q) is a staging system that measures the location, position, and severity of the prolapse relative to the hymenal ring. An anterior compartment–only prolapse was formally referred to as a cystocele, and a posterior compartment–only prolapse was referred to as a rectocele. The uterus or vaginal cuff (if the patient has had a prior hysterectomy) can also prolapse through the vagina in a term called apical prolapse. In the presence of significant anterior compartment prolapse, treatment with reduction of this prolapse may uncover preexisting SUI, so assessment of urinary control with prolapse reduction on exam is essential. Conservative treatment of prolapse consists of a vaginal pessary, which is a plastic or silicone object that is custom fitted to reduce the prolapsed organ.

If a pessary fails to deliver a desirable result, surgical prolapse repair is often undertaken. This can be in the form of anterior, posterior, or apical prolapse repair. Native tissue repairs are now performed for pelvic organ prolapse repair in light of the recent FDA guidance in 2008 and 2011 warning against the use of mesh and prolapse repair due to no increase in effectiveness but an



Needle passed through full-thickness vaginal wall excluding epithelium
Tying of sutures above Cooper's ligament

FIGURE 121.4 Burch colposuspension. (Adapted From Karram MM, Baggish MS. Retropubic urethropexy for stress incontinence. In: Baggish MS, Karram MM, eds. *Atlas of Pelvic Anatomy and Gynecology Surgery.* 4th ed. St Louis: Saunders; 2016. Fig. 71-10.)

increase in risk. Critically, this FDA guidance does not recommend against the use of mesh for SUI procedures, but only for pelvic organ prolapse procedures. For the anterior and posterior repairs, submucosal dissection behind the vaginal mucosa is performed, the prolapsing organ is reduced (bladder for anterior and rectum for posterior), and suture is used to reapproximate the stronger lateral tissues back in the midline. For apical repairs, this can be done transvaginally, in the form of a sacrospinous ligament fixation or uterosacral ligament suspension, or transabdominally, in the form of a sacrocolpopexy. The transabdominal approaches can be open, laparoscopic, or robotic assisted. Conceptually, all apical repairs tether the apex of the vagina/uterus to a more rigid structure, and this can be accomplished via suture or mesh. Alternatively, if the patient is not sexually active, closure of the vaginal vault can be performed in the form of colpocleisis, which actually has high success rates in the well-selected and well-informed patient.

Male

Stress urinary incontinence. Although SUI is less common in males than females, it is a more common situation after surgical procedures on the prostate either for malignancy or BPH. The prostate provides some resistance to urinary flow, and the internal sphincter at the bladder neck is closely aligned with the prostate. In addition, radical prostatectomy can result in harm to the external, striated urethral sphincter as a result of cautery, suture, or overdissection resulting in hypermobility. First-line treatment for SUI after prostate treatment is generally a combination of pelvic floor muscle strengthening (Kegel exercises) and time to allow the muscle to heal. Generally, about 80% to 95% of males with urinary incontinence immediately after surgery will recover to near baseline levels by 1 year after surgery. However, if at 1 year the patient has persistent bothersome and severe incontinence refractory to pelvic floor strengthening, then surgical treatment is warranted. In severe circumstances, some may prefer to even treat at 6 months postoperatively. Cystoscopy before surgical treatment is often recommended to rule out concomitant urethral stricture or vesicle urethral anastomotic stenosis. In males, surgical therapy for SUI is designed to reinforce the urinary sphincter to increase bladder outlet resistance. Typically, treatments are divided into male urethral slings, which have a larger surface area for the mesh suspension material, and artificial urinary sphincter (AUS) devices. Male urethral slings are traditionally reserved for males with mild to moderate urinary incontinence and have an approximately 60% success rate for getting the patient down to zero to one pad per day. On the other hand, an AUS can be used for mild to severe incontinence and has a higher success rate (80%–90%). However, this is a complex device that is implanted in the patient and opened through a one-way valve contained in the scrotum, and as a result this relies on the patient having adequate hand and cognitive function. An AUS, given its complexity and moving parts, often needs to be replaced with a 50% device survival through 10 years.

Benign Prostatic Hyperplasia

BPH is the development of nodules within the prostate gland as a result of enlargement of the stromal and epithelial components of the gland.[20] As the BPH progresses, the entire prostate enlarges in a process called benign prostatic enlargement, resulting in compression of the prostatic urethra and development of bladder outflow obstruction (Fig. 121.5).[20] As part of the bladder outflow obstruction, patients can develop LUTS requiring evaluation and treatment by a urologist. BPH is prevalent, affecting approximately 70% of males between the ages of 60 and 69 years, making it one of the most common conditions treated by urologists.[20] The LUTS that result from BPH can be divided into storage, voiding, and postvoid symptoms. Interestingly, there is little correlation between the measured volume of the prostate and the symptoms that result. In addition, the degree of bladder outflow obstruction does not necessarily correlate with the severity of LUTS.

As with all conditions, evaluation of the patients is centered on the history and physical examination. Key elements of the physical examination include DRE and a focused neurologic examination. Laboratory evaluation includes urinalysis and prostate-specific antigen (PSA) testing in appropriate patients with a life expectancy of more than 10 years (although the use of PSA testing remains controversial). Further evaluation of these patients includes the use of disease-specific validated questionnaires

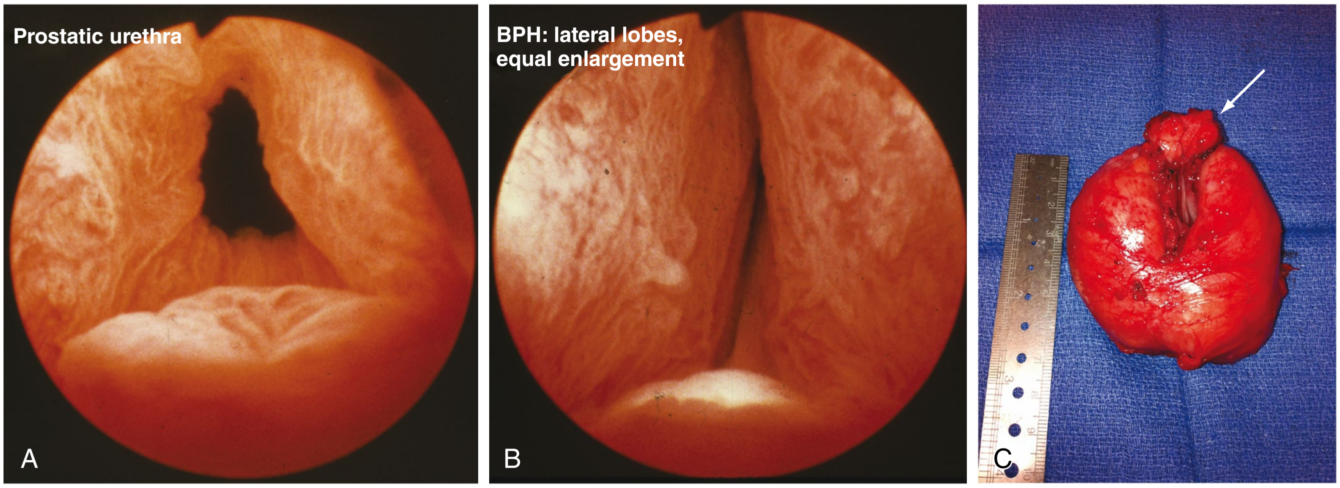


FIGURE 121.5 Benign prostatic hyperplasia *(BPH).* (A) Normal cystoscopic appearance of the prostate in a young male. (B) Moderate BPH, viewed cystoscopically. The size of the prostate correlates poorly with the magnitude of voiding symptoms. (C) Prostatic adenoma after simple open prostatectomy. Note the small medial lobe *(arrow, top center),* with large lateral lobes (130-g specimen).

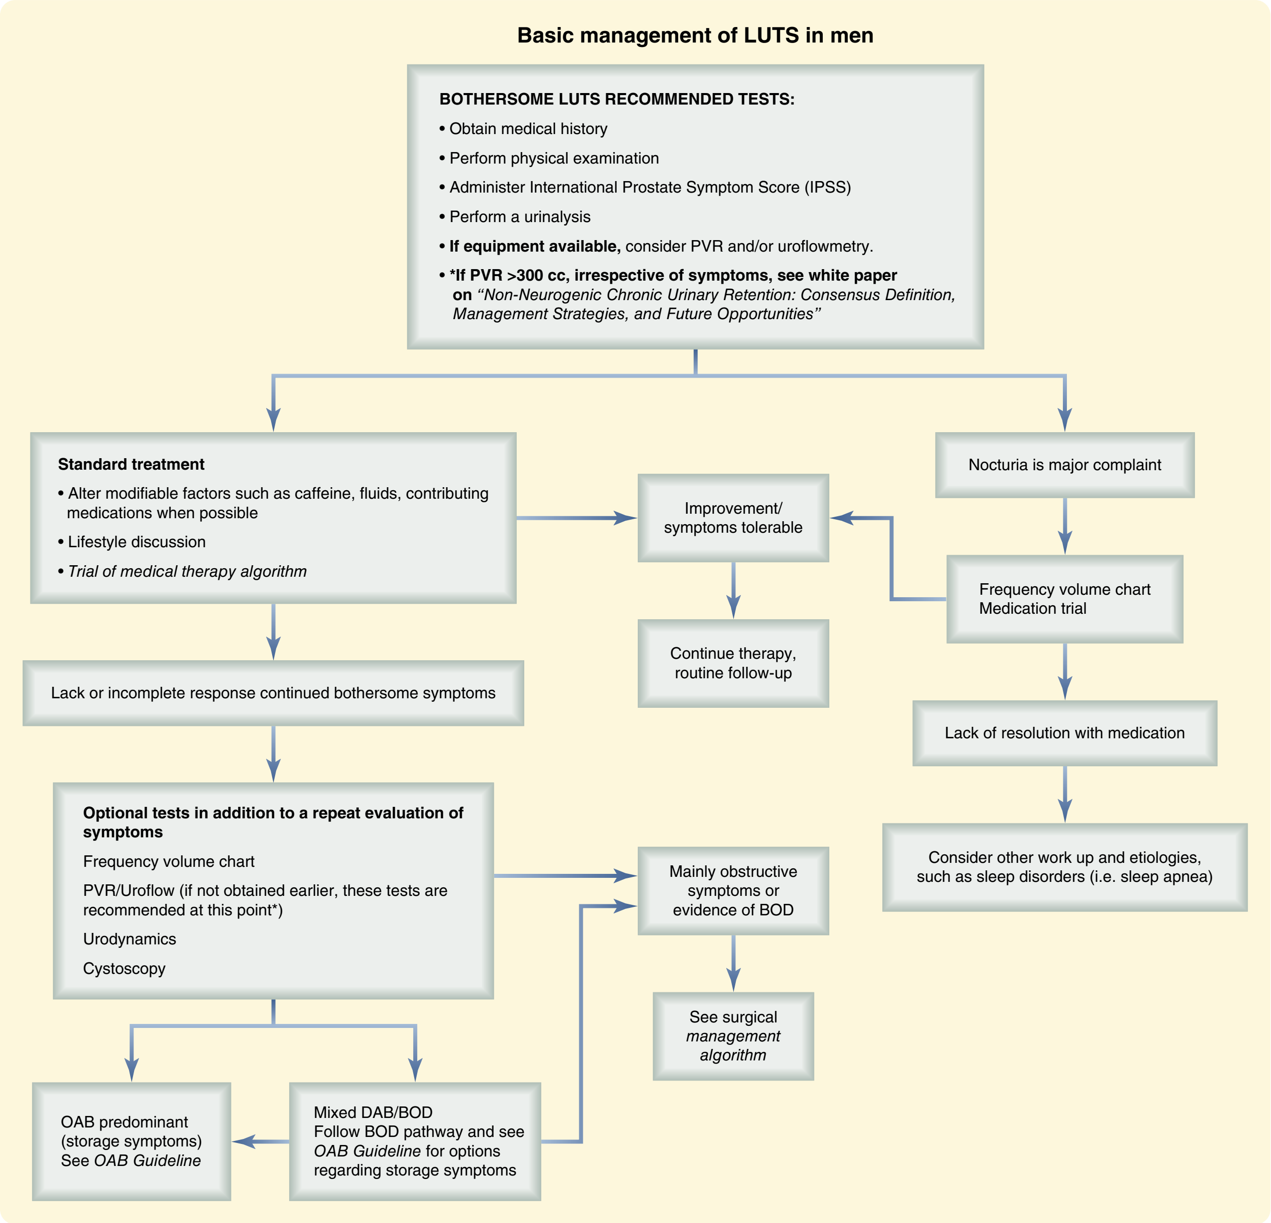
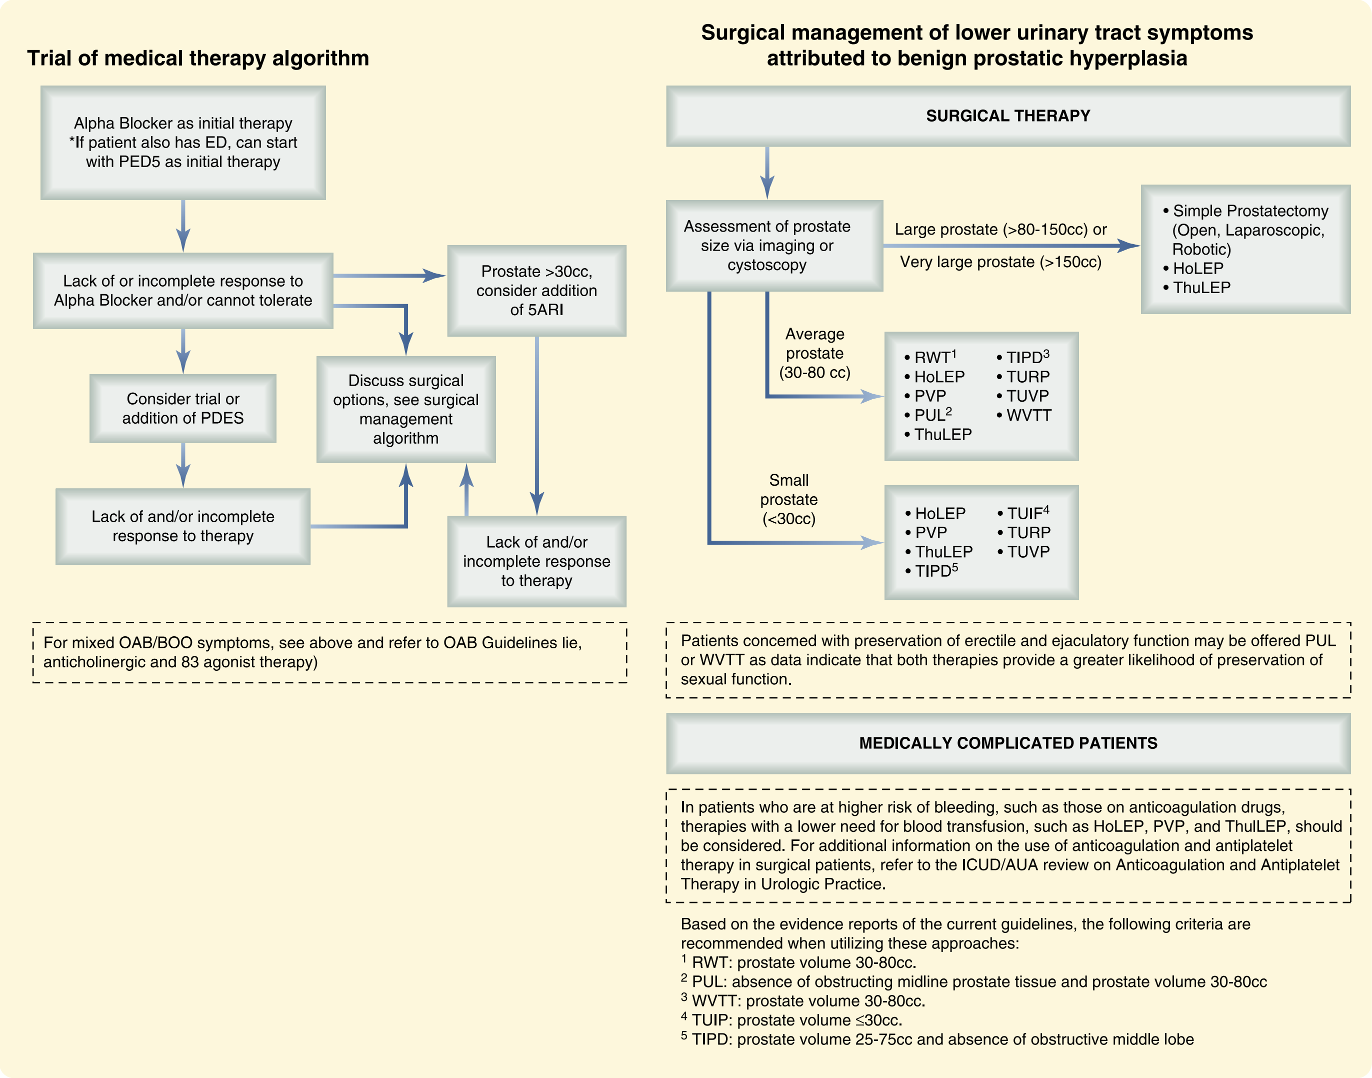
(International Prostate Symptom Score), measurement of postvoid residual urine volumes, and noninvasive urinary flow testing.[20] Depending on initial evaluation findings, cystoscopy and urodynamic studies may be appropriate adjunct tests. Practice guidelines for BPH have been produced by the American Urological Association (AUA) to guide providers in the diagnosis and management of BPH (Figs. 121.6 and 121.7).[20] Similar to all voiding-related conditions, behavior and dietary modifications are appropriate first-step treatment measures in all patients. Medical therapy can be used in conjunction with the initial behavior modifications or added subsequently.

The mainstay of treatment for LUTS due to BPH is α_1-adrenergic receptor blockers.[20] As previously discussed, α-adrenergic receptors are the most common adrenergic receptors in the bladder, and α_1 is the most common subtype in the lower urinary system, prostate, and urethra. The action of α_1-blockers is to relax the smooth muscle in the bladder neck and prostate and to reduce outflow resistance. This class of drugs has become progressively more selective to the α_1 subtypes, and many now target the α_{1a} subtype receptor specifically. The most common side effects of these drugs are dizziness related to orthostasis, retrograde ejaculation, and rhinitis. A second category of pharmacologic therapy is the 5α-reductase inhibitors that target the glandular component of the prostate. These drugs block the conversion of testosterone to dihydrotestosterone in the prostate and subsequently reduce the prostate volume, thereby reducing outflow resistance. This class of drugs also alters the serum PSA level (reduces it about 50%), which must be kept in mind with regard to prostate cancer



Basic management of LUTS in men
BOTHERSOME LUTS RECOMMENDED TESTS:
• Obtain medical history
• Perform physical examination
• Administer International Prostate Symptom Score (IPSS)
• Perform a urinalysis
• If equipment available, consider PVR and/or uroflowmetry.
• *If PVR >300 cc, irrespective of symptoms, see white paper on "Non-Neurogenic Chronic Urinary Retention: Consensus Definition, Management Strategies, and Future Opportunities"
Standard treatment
• Alter modifiable factors such as caffeine, fluids, contributing medications when possible
• Lifestyle discussion
• Trial of medical therapy algorithm
Improvement/ symptoms tolerable
Nocturia is major complaint
Frequency volume chart Medication trial
Continue therapy, routine follow-up
Lack or incomplete response continued bothersome symptoms
Lack of resolution with medication
Optional tests in addition to a repeat evaluation of symptoms
Frequency volume chart
PVR/Uroflow (if not obtained earlier, these tests are recommended at this point*)
Urodynamics
Cystoscopy
Mainly obstructive symptoms or evidence of BOD
Consider other work up and etiologies, such as sleep disorders (i.e. sleep apnea)
See surgical management algorithm
OAB predominant (storage symptoms) See OAB Guideline
Mixed DAB/BOD Follow BOD pathway and see OAB Guideline for options regarding storage symptoms

FIGURE 121.6 Algorithm for initial diagnosis and management of benign prostatic hyperplasia. *LUTS,* Lower urinary tract symptoms; *OAB,* overactive bladder; *PVR,* postvoid residual. (Adapted from Sandhu JS, Bixler BR, Dahm P, et al. Management of lower urinary tract symptoms attributed to benign prostatic hyperplasia [BPH]: AUA Guideline amendment 2023. *J Urol.* 2024;211[1]:11–19.)



Trial of medical therapy algorithm
Alpha Blocker as initial therapy
*If patient also has ED, can start with PED5 as initial therapy
Lack of or incomplete response to Alpha Blocker and/or cannot tolerate
Prostate >30cc, consider addition of 5ARI
Consider trial or addition of PDES
Discuss surgical options, see surgical management algorithm
Lack of and/or incomplete response to therapy
Lack of and/or incomplete response to therapy
For mixed OAB/BOO symptoms, see above and refer to OAB Guidelines lie, anticholinergic and 83 agonist therapy)
Surgical management of lower urinary tract symptoms attributed to benign prostatic hyperplasia
SURGICAL THERAPY
Assessment of prostate size via imaging or cystoscopy
Large prostate (>80-150cc) or
Very large prostate (>150cc)
• Simple Prostatectomy (Open, Laparoscopic, Robotic)
• HoLEP
• ThuLEP
Average prostate (30-80 cc)
• RWT1 • TIPD3
• HoLEP • TURP
• PVP • TUVP
• PUL2 • WVTT
• ThuLEP
Small prostate (<30cc)
• HoLEP • TUIF4
• PVP • TURP
• ThuLEP • TUVP
• TIPD5
Patients concerned with preservation of erectile and ejaculatory function may be offered PUL or WVTT as data indicate that both therapies provide a greater likelihood of preservation of sexual function.
MEDICALLY COMPLICATED PATIENTS
In patients who are at higher risk of bleeding, such as those on anticoagulation drugs, therapies with a lower need for blood transfusion, such as HoLEP, PVP, and ThulLEP, should be considered. For additional information on the use of anticoagulation and antiplatelet therapy in surgical patients, refer to the ICUD/AUA review on Anticoagulation and Antiplatelet Therapy in Urologic Practice.
Based on the evidence reports of the current guidelines, the following criteria are recommended when utilizing these approaches:
1 RWT: prostate volume 30-80cc.
2 PUL: absence of obstructing midline prostate tissue and prostate volume 30-80cc
3 WVTT: prostate volume 30-80cc.
4 TUIP: prostate volume ≤30cc.
5 TIPD: prostate volume 25-75cc and absence of obstructive middle lobe

screening. In addition, these drugs can be used in combination because of their differing mechanism of action, and studies show superior results to either drug used independently.

When medical therapy is ineffective, symptoms remain bothersome, or an objective surgical indication arises (e.g., acute urinary retention, bladder calculi, azotemia, recurrent UTI, or recurrent hematuria), surgical intervention is considered. The standard approach to surgical treatment of BPH is transurethral resection of the prostate (TURP) using various electrosurgical options (monopolar, bipolar, or laser). Minimally invasive treatment options, such as microwave thermotherapy and radiofrequency ablation, can be performed in an office setting but do not have equivalent long-term outcomes compared with standard surgical procedures. When the adenomatous growth is particularly large, open simple prostatectomy is performed to enucleate the adenoma surgically. Outcomes of the transurethral procedures show dramatic improvement in International Prostate Symptom Score numbers, urinary flow rates, and postvoid residual volumes. Procedures such as simple prostatectomy have such a long historical use that objective data have not been measured or compiled, but outcomes are similar to those of TURP. Complications of TURP procedures include persistent bleeding, dilutional hyponatremia from fluid absorption of the glycine irrigation, UTI, urinary incontinence, and urethral stricture. With newer electrosurgical systems (bipolar and laser), normal saline irrigation is used and dilutional hyponatremia has been eliminated. In addition, visualization is improved, with a significant reduction in bleeding complications and a lower incidence of urinary incontinence.

RECONSTRUCTIVE UROLOGY

Urologic reconstructions are often needed for stricture disease or congenital abnormalities that can manifest into adulthood. These problems can impact any point in the urinary tract from the kidney to the meatus and can have varying impacts on quality of life and organ function. Reconstructive urology is a field that takes into account organ function, blood supply, and autologous grafts to address these ailments throughout the urinary tract.

Upper Tract

Ureteral Pelvic Junction

One of the most common functional problems of the upper urinary tract in adults is a ureteral pelvic junction (UPJ) obstruction, which is an anatomic narrowing of the proximal ureter or distal renal pelvis. The narrowing could be extrinsic from a crossing vessel, such as an aberrant branch of the renal artery, or more commonly intrinsic due to an atretic segment. Patients often present with flank pain of the affected side that may be associated with nausea or vomiting and exacerbated by high fluid intake or diuretics, such as caffeine or alcohol. This presentation is classically termed a *Dietl's crisis*. Evaluation is performed often with a renal ultrasound that shows renal pelvic and calyceal dilation without a dilated ureter. However, cross-sectional CT or MRI imaging can also be obtained. Imaging modalities are most helpful during a pain episode to reliably find anatomic dilation suggestive of obstruction. The gold standard radiographic study to find functional obstruction of the kidney is a nuclear medicine mercaptoacetyltriglycine (MAG3) Lasix renogram, which measures the excretion of radioactive tracer from the renal parenchyma into the renal pelvis and to the bladder. This is performed traditionally with a Foley catheter in the bladder to eliminate the possibility of any reflux, and an elimination half-life of over 20 minutes after Lasix administered is considered consistent with obstruction. The study will also provide a measurement of split function between the affected and nonaffected kidney.

Treatment options for UPJ obstruction include observation if the symptoms are mild and the obstruction is relatively low grade, decompression with either a percutaneous nephrostomy tube or ureteral stent, ureteroscopic incision or dilation, or UPJ reconstruction with a pyeloplasty. This can be performed via open, laparoscopic or robotic approaches. There are two common variations of this procedure: a dismembered pyeloplasty (Anderson-Hynes technique) and a nontransecting pyeloplasty (Culp-DeWeerd or spiral flap). A dismembered pyeloplasty is particularly useful in traversing a crossing vessel, and in this procedure the atretic segment of the UPJ is excised and the renal pelvis and proximal ureter are widely spatulated and anastomosed to each other over a stent. In a nontransecting pyeloplasty, the posterior wall of the renal pelvis and ureter are kept intact, and a flap of redundant renal pelvis is sutured as an onlay over the atretic segment to widen the UPJ. Generally, most pyeloplasty techniques have a greater than 90% long-term patency rate.

Ureter

Ureteral reconstructions can be needed due to acute traumatic injuries (frequently iatrogenic) or chronic scarring of the ureter in response to abdominopelvic surgery, ureteroscopy, urolithiasis, or radiation. Extrinsic ureteral compression from tumors or lymph nodes is another cause for ureteral obstruction that require urologist assistance intraoperatively. The options for ureteral obstruction include observation, endoscopic decompression (with the stent or nephrostomy tube), or surgical repair. Evaluation for obstruction again requires a nuclear medicine MAG3 Lasix renogram, and if the kidney is nonfunctional (less than 15% split function), then a nephrectomy of the affected kidney is often the most sensible course. In kidneys with substantial split function, the surgical repair options for ureteral reconstruction depend on the location, length, and density of the stricture or compression. Surgical reconstruction can be performed via open techniques or robotic techniques. The length of the ureter is often roughly divided into proximal (from the renal pelvis down to the lower pole of the kidney), mid (from the lower pole of the kidney down to the iliac vessels), and distal (below the iliac vessels) portions when evaluating for repair. The proximal ureteral reconstructive options are as follows: extended pyeloplasty (for strictures near the UPJ), ureterocalycostomy, or a ureteroureterostomy (for strictures less than 1 cm in length). In certain situations, for certain proximal ureteral strictures downward nephropexy and Boari flap, renal autotransplantation, or creation of an ileal ureter can also be considered. For midureteral reconstruction the options are a Boari flap, a ureteroureterostomy (for strictures less than 1 cm in length), or transureteroureterostomy (which is now largely a historic procedure as it risks damage to the healthy ureter). In recent years, the field has also began employing autologous appendiceal onlay flaps or buccal grafts with encouraging early success rates for well-selected patients with proximal or midureteral strictures. The distal ureteral reconstructive options are usually simpler due to the ability of the bladder to stretch or expand to accommodate a more proximal ureteral insertion. As such, ureteral reimplantation into the bladder is usually performed on its own when the location of stricture is within 4 to 6 cm of the bladder. If there is too much tension on the ureteral anastomosis with a primary ureteroneocystostomy into the bladder, the following maneuvers can be performed to accommodate a longer gap to the healthy ureter: contralateral superior vesicle particle ligation (which detethers the bladder partially from the contralateral pelvic sidewall allowing it to move closer to the affected ureter), ipsilateral psoas hitch (which secures the stretched dome of the bladder to the psoas muscle, bringing it closer to the healthy ureter, with a stitch parallel to the psoas fibers to avoid the embedded femoral nerve), and Boari flap (which is a pedicled full-thickness flap of bladder that is unfurled proximal to the psoas hitch, and has a 3:1 ratio of length to width of the flap). A Boari flap should only be undertaken for large gaps within the bladder in the setting of a healthy bladder with adequate function and capacity.

Lower Urinary Tract

Bladder

Bladder reconstruction is rarely needed after urologic procedures injuring the bladder neck, radiation, or neurogenic causes of bladder dysfunction. In some circumstances of small bladder capacity, a bladder augmentation is needed, and this can be performed with a enterocystoplasty, using either small bowel or large bowel to augment the capacity of the bladder. In addition, bladder reconstruction is also required for advanced primary bladder malignancy, which necessitates removal of the bladder and urinary diversion with either an ileal conduit, ileal neobladder, or least commonly a continent cutaneous catheterizable pouch. An ileal conduit is the most common urinary diversion used for bladder cancer and consists of a 12- to 20-cm segment of terminal ileum used to create an ostomy on the distal end and ureteroenteric anastomoses on the proximal end. An ileal neobladder uses a 55- to 60-cm segment of ileum, with the proximal 10 to 15 cm used as a stump for the ureteroenteric anastomosis and the remaining bowel detubularized and then sutured into a roughly spherical confirmation for anastomosis into the remnant urethral stump.

Electrolyte abnormalities are common when bowel is used for urinary augmentation or replacement. Most commonly, when ileum is used, a hyperchloremic metabolic acidosis can result, which in turn may decrease bone density. As a result, sodium bicarbonate is recommended to correct this. Additionally, B_{12} deficiency can develop due to lack of intrinsic factor reabsorption from the ileum that is now excluded from the alimentary canal for the urinary diversion.

Urethra

Strictures of the urethra are a common cause of LUTS such as slow stream, prolonged voiding, impaired sense of bladder emptying, and need to augment bladder pressure with Valsalva voiding or manual pressure on the bladder (Credé maneuver). Due to the incomplete bladder emptying, they may also predispose to UTIs and in severe cases, bladder hypertrophy and upper tract deterioration. Urethral strictures are far more common in males than in females. Common causes of urethral stricture disease include urethral instrumentation with catheters or scopes, lichen sclerosis (which is an inflammatory lesion of the skin and urethral mucosa), trauma, ischemic insult to the bulbomembranous urethra (such as during prolonged hypotension from major surgery), and radiation. Malignancy can also be a less common cause of stricture, but this needs to be higher on the differential in cases of recurrent urethral stricture or atypical appearance on imaging.

The male urethra is divided from distal to proximal as the following: urethral meatus, fossa navicularis, pendulous urethra, bulbar urethra, membranous urethra, and the prosthetic urethra. The available options for stricture treatment depend on the location, length, diameter, and density of the stricture. The location and length of the stricture is best characterized with a retrograde urethrogram performed under fluoroscopy, and the diameter and density of the structure is best characterized with direct visualization under cystoscopy.

Strictures involving the urethral meatus or fossa navicularis are often treated with dilation or endoscopic incision or open incision of the meatus (meatotomy). Endoscopic dilation or incision can also be used for thin urethral strictures less than 2 cm in length for the bulbar urethra as well. For strictures not amenable to endoscopic management, an option of indwelling urethral or suprapubic tube or intermittent self-catheterization exists for patients who are not surgical candidates. Urethroplasty remains the gold standard for meatal/fossa strictures that are recurrent after endoscopic management, any primary penile urethral stricture, bulbar urethral strictures over 2 cm in length, or bulbar urethral strictures less than 2 cm that are recurrent after endoscopic management. Urethroplasty can be performed with an excision of the involved urethral segment followed by primary anastomosis with wide spatulation. This excision and primary anastomosis are mainly performed for short segment strictures of the bulbar urethra. For longer strictures of the bulbar urethra and most strictures of the penile urethra in which primary anastomosis would have tension, an oral mucosal graft (buccal or lingual) augmentation urethroplasty is the gold standard. For even longer segment strictures, two-stage procedures in which the graft is first placed and then tubularized to completely substitute an excised segment of urethra can also be performed. It is important not to use hair-bearing skin for augmentation or substitution urethroplasty. For proximal urethral strictures involving the prosthetic and membranous urethra, more complex reconstruction is needed and often involves augmentation with oral mucosal graphs.

In females with urethral strictures, treatment options often start with endoscopic dilation or incision for simple strictures, but oral mucosal grafts or vaginal and advancement flaps can be used to incise and then widen the diameter of the urethra.

MALE REPRODUCTIVE MEDICINE AND SEXUAL DYSFUNCTION

Male infertility and sexual dysfunction are a specialized area of urologic practice. Diagnostic evaluation, medical treatment, and surgical therapy of male infertility represent sophisticated aspects of urologic care. Male sexual dysfunction is becoming more prominent as the field of male health continues to evolve. Many patients seen and evaluated by general surgeons may be receiving specific medical therapy or have undergone prosthetic surgical implants for sexual dysfunction management. A basic familiarity with these specialized areas is beneficial to general surgeons in their surgical practice.

Male Reproductive and Sexual Dysfunction: Evaluation and Treatment

Infertility affects approximately 8% to 14% of couples; the male factor is the primary or sole factor in 36% to 75% of these cases.[21] Couples are often referred to the urologist after a period of infertility, and referrals are generally from a primary care physician or from the evaluating gynecologic reproductive endocrinologist. Infertility is defined as a couple's inability to achieve pregnancy after 1 year of unprotected intercourse.[21]

The standard male factor evaluation involves a detailed history, physical examination, and basic laboratory and imaging evaluation. The AUA has produced a series of best practice statements on the evaluation of the infertile male with the following objectives: to recognize and to treat reversible conditions, to categorize disorders potentially amenable to assisted reproductive techniques, to identify syndromes and conditions that may be detrimental to the patient's health, and to distinguish genetic abnormalities that can be transmitted to or affect the health of offspring.[22]

The causes of infertility can be divided into anatomic, behavioral and environmental, and iatrogenic. Anatomic causes of male infertility are either congenital or acquired.[21] The most significant anatomic cause is congenital absence of the vas deferens, which is a partial or complete agenesis of the vas deferens. Although uncommon, the finding is associated with a cystic fibrosis transmembrane conductance regulator (CFTR) gene mutation, making these patients carriers for cystic fibrosis.[22] Other anatomic findings include cryptorchidism, ejaculatory duct obstruction (at the level of the prostate), and varicocele (Fig. 121.8). Behavioral and environmental sources of infertility are more common and easier to reverse than anatomic causes of male infertility. These include obesity, environmental exposures, substance abuse (including exogenous testosterone), and vitamin deficiency. Finally, iatrogenic causes to be considered include prior chemotherapy or radiation therapy, prior inguinal or genital surgery, and current medical treatments. Surgeons must be aware of iatrogenic causes of infertility in groin and pelvic surgical procedures from damage to the spermatic cord vasculature, vas deferens, and ejaculatory duct region or vasal entrapment from mesh used for inguinal hernia repair. The blood supply to the vas deferens or testicle is vulnerable to injury when the groin is explored in reoperative surgery or when the anatomy is obscured because of inguinal trauma as identification of these structures is challenging.

The history should include a discussion of sexual and reproductive history. This includes potential gonadotoxic exposure;

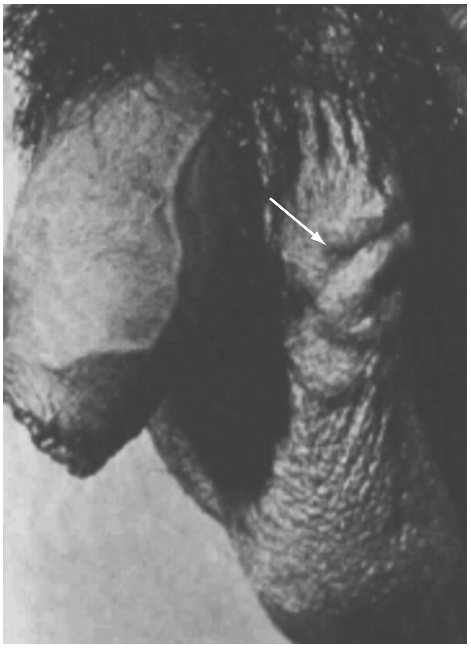

FIGURE 121.8 Varicocele. The bag of worms appearance is visible *(arrow)* and palpable through the scrotal skin, representing the dilated branches of the internal spermatic venous system.

urologic infections and STIs; trauma and prior surgery involving the pelvis, groin, and genitalia; and family history of infertility. Physical assessment should include a general evaluation of masculinization and genital findings, including normal meatal location, testicular size and consistency, presence and normalcy of the epididymis and vas deferens, and possible presence of a varicocele. Perineal and rectal examinations are routine parts of this assessment.

Basic Laboratory Assessment

Laboratory evaluation of these patients includes two semen analyses and serum hormone studies. The semen analyses should be separated by 1 month and preceded by 2 to 3 days of abstinence. Semen analysis parameters of importance include semen volume, pH, sperm concentration and total count, total motility, progressive motility, quality of sperm movement, morphology, and presence of red and white blood cells or bacteria.[21] The World Health Organization (WHO) has defined parameters of normal for routine semen analyses.[21] Semen analysis abnormalities fall into two main categories: azoospermia (the complete absence of sperm from the semen) and abnormal semen parameters (reduced concentration, motility, or morphology and abnormal function). Azoospermia can roughly be divided into three categories: pretesticular, testicular, and posttesticular. Pretesticular azoospermia results from endocrine causes, such as hypogonadotropic hypogonadism, or congenital causes. Testicular causes are the result of primary testicular failure of germinal epithelium of the testis to produce mature sperm. This is often accompanied by normal semen volume and by a markedly elevated serum follicle-stimulating hormone (FSH) level. Posttesticular causes, such as ejaculatory dysfunction and obstruction, account for 40% of cases of azoospermia.[22] Abnormal semen parameters may be indicative of a wide range of disorders that may cause reduced sperm numbers, motility, or morphology, including varicocele, antisperm antibodies, genital duct infection with pyospermia, and prior or current gonadotoxic exposure. Reduced semen volume may be artifactual, indicating incomplete ejaculation or specimen collection, or it may represent true disease, including, for example, congenital absence of the seminal vesicle, ejaculatory duct obstruction, or retrograde ejaculation caused by diabetes, neurologic injury, or previous bladder neck surgery or medications.

Serum hormone testing includes determination of levels of FSH, luteinizing hormone, testosterone, free testosterone, and prolactin. Hypogonadotropic hypogonadism may be diagnosed on the basis of serum hormone studies or elevation in the FSH level. A patient with a low testosterone level should have follow-up prolactin levels measured to rule out a prolactinoma of the pituitary gland.

Ultrasound of the scrotum is useful to measure testicular volume and symmetry, to exclude the possibility of testicular neoplasm, to identify epididymal anatomy, and to define or to confirm the presence of a varicocele, which is an abnormal dilation of the pampiniform venous plexus of the internal spermatic venous system (see Fig. 121.8). Transrectal ultrasound (TRUS) of the prostate may provide evidence of ejaculatory duct obstruction with seminal vesicle dilation or congenital absence of the seminal vesicle, which may accompany congenital absence of the vas deferens.

Treatment

Treatment of male infertility depends on the identified cause and on the availability and affordability of assisted reproductive technology support options for specific or empirical treatment of failure to conceive. Medical therapy is used to treat hormone deficiencies, hormone excess, thyroid hormone excess, and prolactin excess. The most common medical therapies include hormonal stimulation of spermatogenesis, such as gonadotropin agents and antiestrogen agents, which have been met with mixed results. Antiinflammatory or antibiotic therapy can be used in patients with findings of pyospermia or concern for genital duct infection. Surgical therapies may include microsurgical reconstruction for vasal or epididymal occlusion (including vasectomy reversal), transurethral resection of the ejaculatory duct for obstructive lesions, and varicocele repair.

Male Sexual Dysfunction and Treatment

Sexual dysfunction in males refers to a range of disorders, including erectile dysfunction (ED), diminished libido, hypogonadism, and ejaculatory dysfunction. Because of the numerous organ system interactions, patients with these conditions may have associated neuropathy, endocrinopathy, vasculopathy, and psychological disorders, and these abnormalities may affect nonneurologic patient management and surgery.

Normal erectile function is a complex interaction between the nervous and vascular systems, with unique molecular actions occurring in penile vascular structures. Many medical comorbidities and lifestyle choices can contribute to ED, including age, coronary artery disease, smoking, hypertension, dyslipidemia, atherosclerosis, peripheral vascular disease, obesity, diabetes, spinal cord injury and degenerative neurologic conditions, treatment of pelvic malignant neoplasms, and chronic kidney disease.[23] The causes of ED can be divided into neurologic, vascular, metabolic, medication induced, endocrine, and psychological; importantly, it can be an early marker for coronary artery disease.[23] The initial evaluation of the ED patient centers on the history and physical examination. The history is focused on sexual performance and erectile function; the nonsexual historical aspects center on possible medical and surgical conditions. Social aspects, such as smoking, recreational drug use, and diet, are also important considerations. Validated questionnaires provide objective historical data both for initial treatment and for evaluation of therapy outcomes. The physical examination centers on the genitalia and evaluation of male secondary sexual characteristics. Basic laboratory studies in these patients include morning total testosterone concentration, fasting lipid levels, and hemoglobin A1c level. Important consideration should be given to assessment of cardiovascular function in younger patients because this disease process is considered an early marker for cardiovascular disease, especially in younger patients. Further evaluation is specialized but may include neurologic testing (e.g., biothesiometry) and vascular testing (e.g., penile duplex Doppler ultrasound studies).

Most treatments for ED are based on restoring penile arterial blood flow to achieve or to maintain a satisfactory erection. Lifestyle modifications are an important component of this, and dietary changes and increased regular cardiovascular exercise have been shown to independently improve erectile function. Evaluation and adjustment of offending medications should be considered as well. The basis of medical therapy for ED is phosphodiesterase type 5 inhibitors. These medications improve penile blood flow by limiting the breakdown of cyclic guanosine monophosphate and potentiating penile blood flow. These drugs should be limited in their use in males with known cardiovascular disease, especially those taking oral nitrates. Other forms of nonsurgical treatment include vacuum erection devices, intraurethral suppository therapy with prostaglandin compounds, intracavernosal self-injection, and occasionally psychotherapy. Surgery for ED includes primarily placement of a penile prosthesis and limited vascular reconstruction. Penile implant surgery may involve malleable implants, which have a flexible wire core inside a silicone sleeve, implanted bilaterally in the corpora, or, more commonly, inflatable penile implants. These are fluid-containing, completely internalized systems that may include paired corporal cylinders, a scrotal pumping device, and a fluid reservoir, which is typically positioned in the retropubic space or extraperitoneal lower abdominal quadrant (Fig. 121.9). The general surgeon should be aware that intraperitoneal positioning may also occur, intentionally or through erosion through the peritoneal membrane, and the reservoir or system tubing may be encountered during nonneurologic abdominopelvic surgery. Care should be taken not to contaminate any of the implant components or inadvertently injure the tubing or device components. If it is known that an implant is in place and pelvic or inguinal surgery is planned, urologic consultation may be helpful in handling any issues that arise with the implant. Revascularization of the penis to restore erectile function, following arteriography for anatomic documentation, is usually achieved using an inferior epigastric artery pedicle flap, whereby new arterial inflow is brought to the corpora cavernosa. This has limited indications, most relevant in younger patients with traumatic injury to the pelvic blood supply, and national practice guidelines consider this to be controversial.

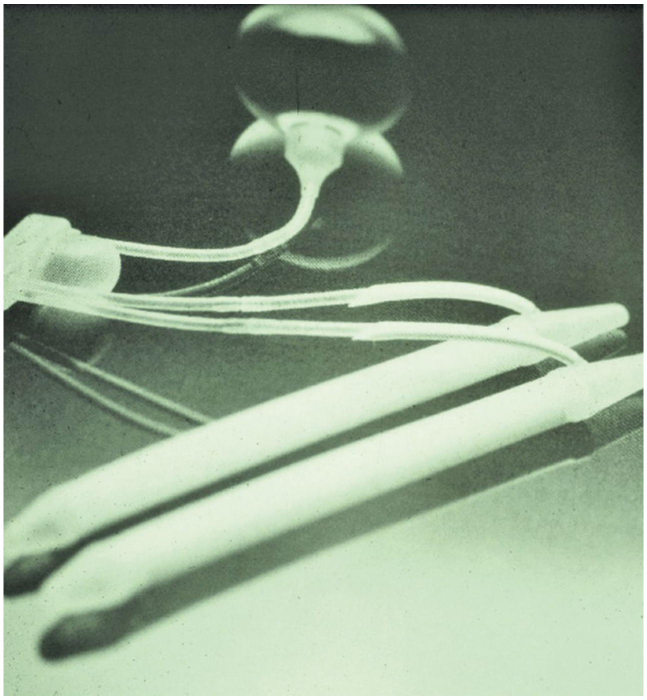

FIGURE 121.9 Inflatable penile prosthesis. A three-component device is shown. The reservoir *(top)* is placed retropubically in an extraperitoneal position. The paired cylinders *(right)* are placed within the corpora cavernosa. The pump *(left)* is placed in the scrotum, adjacent to the testes.

The other area of male sexual medicine affecting a significant number of patients is testosterone deficiency or hypogonadism. Serum testosterone is produced in the Leydig cells of the testes (90%) and adrenal glands (10%). Testicular synthesis of testosterone is controlled by the hypothalamus and anterior pituitary. This is a condition in which serum testosterone levels decline and are associated with symptoms of fatigue, lack of energy, depressed mood, irritability, reduced motivation, decreased cognitive acuity, decreased strength and stamina, reduced muscle mass and increased fat, and sexual side effects including decreased libido and ED. There is a normal age-related decline in testosterone as males age, and total testosterone declines by 1%, on average, each year after the age of 40 years. The prevalence of this condition is between 2.1% and 39% of males older than 40 years, depending on the criteria used and association of symptoms.[24] The patient's history should elicit information on the specific symptoms of testosterone deficiency, and physical examination is similar to that for ED with evaluation of the genitalia and secondary sexual characteristics. Validated questionnaires are useful to assess and to monitor therapy. Laboratory studies should include free and total morning testosterone, luteinizing hormone, prolactin, hematocrit, and hemoglobin levels.[25] Therapy for testosterone deficiency is based on lifestyle modifications and testosterone supplementation.[25] Many males who suffer from this condition are either obese or have metabolic syndrome. Dietary changes to improve nutritional status and to result in weight loss have been shown to improve not only baseline medical conditions but also serum testosterone levels. Furthermore, moderate-intensity exercise has been shown to improve serum testosterone levels. In addition to lifestyle modifications, many patients are treated with supplemental testosterone. Synthetic testosterone may be administered orally, transdermally, through intramuscular injections, and by subcutaneous pellets. The goal of therapy is maintenance of testosterone levels between 400 and 700 ng/dL and resolution or improvement of presenting symptoms.[25] Although there are few absolute contraindications to testosterone administration, many potential adverse side effects exist and should be discussed before administration of these medications as this is the area of greatest controversy with testosterone supplementation. Potential adverse effects include cardiovascular events and mortality, dermatologic changes, polycythemia, diminished spermatogenesis, gynecomastia, LUTS, prostate cancer, and sleep apnea.[25]

UROLITHIASIS

Urinary tract stones are a common cause of visits to the emergency department. The prevalence of renal calculous disease in the United States is increasing, with a lifetime risk of forming a renal stone at 5% in 1994 and 9% in 2010.[26] The incidence of stone disease peaks in the fourth to sixth decades of life and is more common in males than in females by a 2:1 margin.[26] Renal calculous disease has several aspects of management and evaluation, including acute stone presentation, metabolic evaluation, and medical and surgical therapy. As most general surgeons will encounter patients either in the acute presentation or around the time of surgical intervention, this section focuses on these areas.

Background

The pathogenesis of calculus formation is governed by the physical chemistry characteristics of the urine in the upper collecting system. Most stones are formed by minerals or stone-forming salts and begin to crystallize when their concentration becomes supersaturated in the urine. Just as certain minerals or salts promote calculus formation, there are many inhibitors of calculus formation, including citrate, phosphate, and magnesium. There are many theories to stone formation, none of which are definitively proven, such as Randall plaque formation, stasis, bacteria, and reactive oxygen species from oxalate excretion.[27] Kidney stones are classified by the stone composition, and the mineral composition directs evaluation, treatment, and nonsurgical management. Kidney stones can be generally classified as calcium based, uric acid stones, struvite stones, and cystine stones.[27] Calcium stones are usually composed of two calcium salts, calcium phosphate and calcium oxalate, and are the most common renal calculi. Risk factors for calcium stone formation include abnormal urine pH; high urine concentration of calcium, oxalate, or uric acid; and low urine concentration of the stone inhibitor citrate. Uric acid stones form in a low pH urine in patients with hyperuricosuria and can be the result of purine metabolism from cellular breakdown (tumor lysis) or excessive protein intake. These stones are often radiolucent. Struvite stones, also called infection stones or magnesium ammonium phosphate, result from specific bacterial infections (*P. mirabilis, K. pneumoniae, Staphylococcus aureus,* and *Staphylococcus epidermidis*) that contain urease, which converts urea into ammonia. The base properties of ammonia lead to higher urine pH and crystallization with phosphate. Cystine stones are formed from an autosomal recessive defect in the metabolism of the COLA amino acids (cystine, ornithine, lysine, and arginine), which results in elevated urine cystine levels.[27] The other rare cause of calculi is pharmacologically induced, resulting from poor drug metabolite urine solubility and precipitation in the urine. The most notable of these are protease inhibitors (indinavir and ritonavir), which are not visible on noncontrast CT scans.

Acute Presentation and Management

Patients presenting with an acute stone episode or renal colic typically have characteristic complaints of abdominal, flank, or back pain that waxes and wanes but cannot be resolved with position changes. Often, these patients can localize the most intense center of the pain, giving some indication of stone location. When the ureter is obstructed by a stone, the pressure in the proximal collecting system rises, and with progressive distention, the patient may experience visceral symptoms, including nausea, vomiting, and ileus. Physical examination in these patients should be focused on the back, flank, abdomen, and genitalia. Patients who have specific vital sign findings in combination (temperature higher than 101.5°F, hypotension, or tachycardia) should be assessed for obstructive upper tract UTI with the potential for sepsis. Basic laboratory evaluation should include complete blood count, metabolic panel, and urinalysis with microscopy. Significant findings of leukocytosis or acute kidney injury may direct urgency of therapy and type of intervention. A noncontrast-enhanced CT scan of the abdomen and pelvis is the preferred imaging study because of its superior sensitivity and specificity compared with intravenous urography and plain radiography. Patients with ureteral calculi may benefit from a plain radiograph, as 85% of calculi are radiopaque, to observe for stone passage.

Once the stone is identified and the location established, pain management is the next step. Patients who are diagnosed with renal or ureteral calculi should receive intravenous nonsteroidal antiinflammatory drugs (ketorolac) or opioid analgesics as initial therapy. A successful attempt at pain control with oral agents determines whether the otherwise hemodynamically stable patient can be discharged or requires inpatient treatment for the stone. Those patients who present with upper tract UTI and obstruction should undergo expeditious drainage with either cystoscopic ureteral stent placement or percutaneous nephrostomy tube placement. If one upper tract is totally obstructed by stone, the patient could have a serious infection with pyonephrosis, and the voided urine would be deceptively normal. Patients who are suitable for hospital discharge include those with no evidence of UTI, hemodynamic stability, good oral intake, pain well controlled on oral analgesics, and a stone size with reasonable chance of spontaneous passage. In patients who are discharged from the hospital, medical expulsive therapy, with agents to promote spontaneous stone passage, is the recommended management.[28] The most common drug used is tamsulosin, the α_{1a}-blocker that relaxes ureteral smooth muscle.[28] If a patient is discharged for outpatient management, they should be observed closely to determine whether the stone has passed. It should not be assumed that because the pain has resolved, the stone has passed. With persistent upper tract obstruction, the pressure in the collecting system eventually declines as renal blood flow diminishes and urine output drops. The patient's pain can disappear, and the kidney can remain obstructed, undergoing silent destruction in the weeks and months that follow. Reimaging is necessary if there is no definitive evidence that the stone has been passed (e.g., the patient brings it in for analysis).

Elective Diagnostic Evaluation and Management

Patients who are diagnosed with asymptomatic renal calculi, such as nonobstructing renal calyceal stones found incidentally during a hematuria evaluation, and patients who have convalesced after an acute presentation undergo a basic metabolic screening evaluation. Important historical aspects to obtain include prior stone passage or treatment, family history, bowel disease or malabsorption, gout, hyperthyroidism, obesity, and use of dietary supplements.[29] Routine laboratory work includes urinalysis, basic metabolic panel with determination of calcium and uric acid levels, urine culture, and stone analysis (if available). A 24-hour urine specimen is also collected to evaluate the urine for specific chemical and mineral content: volume, pH, creatinine, calcium, oxalate, uric acid, citrate, sodium, and potassium.[29] Specific dietary changes and medical therapy can be used for prevention of stone formation in specific populations. These dietary modifications and pharmacologic treatments are based on stone composition and findings on 24-hour urinalysis. The two most common stone types, calcium and uric acid, are discussed.

In patients with calcium-based stone disease (oxalate or phosphate), the single most important treatment or dietary modification is increased fluid intake to achieve more than 2 L of urine output daily. In addition, there should be no changes in calcium consumption, and patients, in general, should consume the recommended daily allowance of dietary calcium. Dietary levels of sodium, foods high in oxalate, and animal protein should be reduced as each of these can affect urinary oxalate and citrate levels. Pharmacologic therapy is typically based on three different agents, thiazide diuretics, potassium citrate, and allopurinol, each of which has separate effects on calcium urine levels and calcium stone formation. Patients with uric acid stones are treated with drug therapy.[29] There are no dietary recommendations other than to increase fluid intake to raise urine output to 2 L/day. Pharmacologic therapy in this group consists of potassium citrate and allopurinol. Many uric acid stones can be dissolved by raising urinary pH levels with use of alkalinizing agents.

Elective Surgical Management

Patients who have large stone burdens or continue to have symptomatic stones require surgical treatment of their calculous disease. Surgical treatment of renal and ureteral calculi varies from completely noninvasive, shock wave lithotripsy (SWL), to minimally invasive, percutaneous nephrolithotomy (PCNL). SWL is a transcutaneous procedure using generated shock waves to fragment stones. Shock waves create positive and negative pressure components that are focused on the stone and create fractures in the targeted stones, ultimately resulting in stone fragmentation.[30] The progress of stone fragmentation is monitored during SWL, typically with fluoroscopy, to direct treatment length and location. Nonradiopaque stones, stones larger than 2 cm, dense stones, and certain ureteral calculi should not be treated with this method. Complications from SWL include renal injury, steinstrasse (street of stones), hypertension, and chronic kidney disease.[30]

Smaller renal stones and ureteral calculi can be managed in an endoscopic fashion using ureteroscopes (Fig. 121.10). As previously mentioned, ureteroscopes are both semirigid and flexible, allowing full upper tract collecting system access. Through the working channel of ureteroscopes, a variety of working instruments can be placed to fragment or to remove stones. The most common stone treatment is laser lithotripsy to completely fragment the symptomatic calculus. Smaller fragments can be removed using different basket and grasping systems to render the patient stone free. Complications of ureteroscopy include acute ureteral perforation or avulsion, UTI, and late ureteral stricture formation.

For larger renal stones or select proximal ureteral stones, PCNL is preferred because of the larger working endoscopes and better instrumentation for stone fragmentation. The basic steps of PCNL are percutaneous renal access, dilation of the nephrostomy track, placement of the working sheath for stone fragmentation and extraction, and postoperative renal drainage. The advantage of PCNL is that numerous intracorporeal lithotripsy devices are available, and large stones can be rapidly fragmented. Flexible nephroscopes can also be used in this setting. Complications of PCNL are most significant because of the more invasive nature of the procedure; these include sepsis, renal hemorrhage, renal collecting system injury, and damage to adjacent organs and viscera. PCNL may result in hydrothorax or pneumothorax from transpleural or peripleural access tracks that requires evacuation. With the refinement of PCNL, open stone surgery is rarely indicated even for the most complex intrarenal calculi. Laparoscopic and robotic procedures for specific renal calculi have been described.

NONTRAUMATIC UROLOGIC EMERGENCIES

Within the field of urology are several emergent conditions, although not due to external violence, that represent true emergencies, some of which are life threatening. These urologic emergencies include obstructed upper tract UTI, hematuria with urinary retention due to blood clots, and the acute scrotum, specifically testicular torsion, priapism, and Fournier gangrene. Some of these conditions have been discussed in other sections of this chapter (Fournier gangrene and obstructed upper tract UTI); the remainder are covered in this discussion.

Testicular Torsion

The most urgent cause of the acute scrotum is testicular torsion. Testicular torsion occurs when arterial blood supply is compromised by a twist of the spermatic cord, creating occlusion of the spermatic cord and loss of vascular supply. In the normal anatomic arrangement, the inferior aspect of the testicle is attached

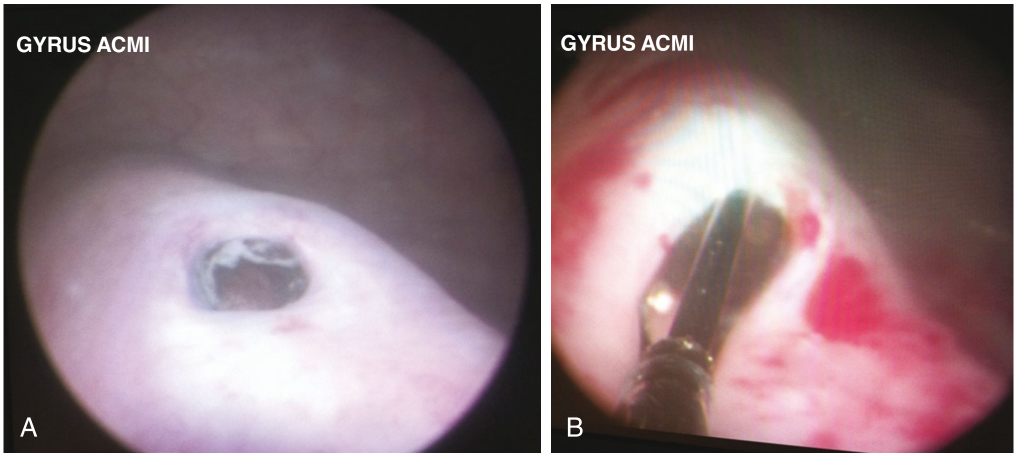

FIGURE 121.10 Ureteral stone. (A) An obstructing calculus is shown crowning within the right ureteral orifice. (B) Cystoscopic extraction performed with a grasping forceps.

to the scrotum by the gubernaculum, preventing rotation of the testicle within the scrotum. When torsion occurs, the testicle is subjected to warm ischemia; without reversal of the occluded blood supply, irreversible damage begins as soon as 4 hours and is complete by 8 to 12 hours. Although testicular torsion is most common in adolescent males, it may occur in any age group from neonate to adult males. As many other conditions may result in the so-called acute scrotum, a high index of suspicion is necessary on the part of the treating physician to ensure rapid diagnosis and treatment. Differential diagnosis includes trauma, epididymitis, incarcerated hernia, and torsion of the appendix testis or appendix epididymis. Diagnosis is strongly suspected on the basis of history and physical examination. Classic historical findings include sudden onset of intense unilateral scrotal pain, unrelated to trauma, that may be associated with nausea and vomiting. The most consistent physical examination finding is loss of the cremasteric reflex of the testicle; however, in an acute setting, this may be difficult to elicit. The best confirmatory radiologic study is color Doppler ultrasound of the scrotum, which shows absence of arterial flow to the testis in torsion. In patients with suspected testicular torsion, there is no need to delay scrotal exploration to obtain imaging or further laboratory evaluation.

Treatment of testicular torsion involves surgical exploration through a midline or transverse scrotal incision with inspection of the testis with detorsion of the spermatic cord if present (Fig. 121.11). For testes that are deemed to be viable, suture orchiopexy or fixation to the interior scrotal wall is performed, followed by a similar orchiopexy on the contralateral side at the same setting to prevent contralateral torsion. Because of the important medicolegal considerations in these cases, urgent exploration is still indicated even in patients who present with a suspected late torsion (e.g., several days of fixed swelling, firmness). Many times, it is difficult to know exactly how long complete ischemia has been present and whether there is still a potentially viable testicle.

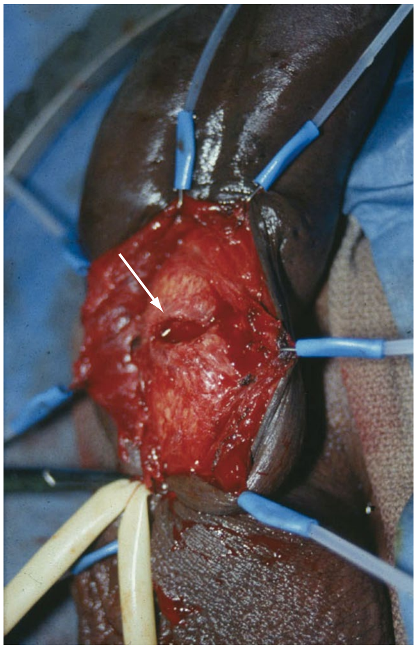

FIGURE 121.11 Testicular torsion. Exploration through a transverse scrotal incision demonstrates the twisted cord *(top)*. Note the degree of edema, erythema, and ecchymosis present after several hours of torsion.

Gross Hematuria With Urinary Retention From Blood Clots

Most patients who have hematuria present with either microscopic hematuria or episodic gross hematuria. However, in a subset of patients, onset of gross hematuria is rapid with significant blood loss and development of blood clots within the bladder. This problem is exacerbated in patients who are receiving chronic anticoagulation for underlying cardiovascular disease processes. The blood clots are organized into larger masses; the patient may not be able to expel the clot, leading to urinary retention and a potential surgical emergency (Fig. 121.12). Other causes of significant vesical hemorrhage include postoperative bleeding after TURP or transurethral resection of bladder tumor (TURBT), radiation cystitis, pelvic trauma, upper tract arteriovenous fistula, and iliac arterial fistula to the ureter.

It is difficult to judge the amount of blood that is being lost from the urinary tract with gross hematuria because only a small amount of blood mixed with urine will darken the bladder efflux. If, however, copious amounts of clot are evacuated from the bladder, one should suspect at least moderate blood loss and monitor the patient with vital signs and hemoglobin measurements. If bleeding from these events causes symptomatic anemia, the patient may require multiple urgent blood transfusions. In the patient with a significant amount of blood clot in the bladder, it will be necessary to place a large-bore irrigation catheter (in the adult, often 20–26 Fr) and adequately irrigate the clots from the bladder using normal saline irrigation. Special hematuria catheters are designed to allow large-volume irrigation and clot removal, but if this is unsuccessful, the patient may require urgent operative cystoscopy to evacuate the clot and to identify and fulgurate any bleeding source. Typically, this involves rigid cystoscopy with a large working sheath or resectoscope sheath and irrigation performed with a piston syringe or special evacuation devices (Ellik evacuator). After clot evacuation and fulguration, a large three-way catheter is left in place to run continuous irrigation to prevent a recurrent episode of clot retention. Upper tract clot formation may produce a so-called clot colic, with renal pain similar to that experienced from passage of a renal calculus. Supportive care and,

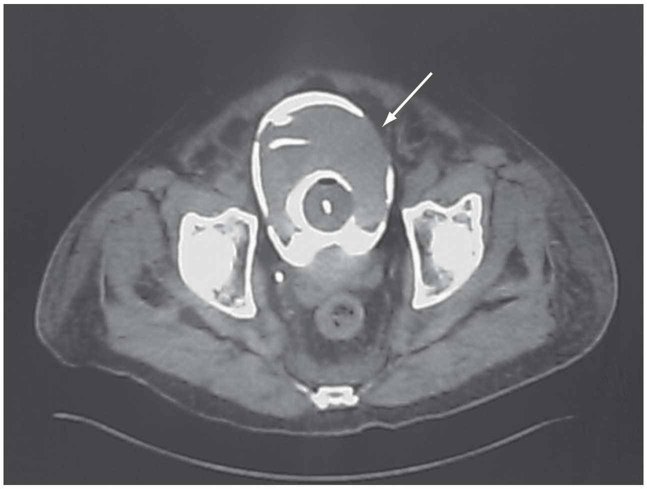

FIGURE 121.12 Computed tomography scan of the pelvis with cystography in a patient with urinary clot retention caused by chronic hemorrhagic cystitis after radiation therapy for prostate cancer. A clot may be seen surrounding the Foley catheter balloon, with instilled contrast material outlining the balloon and intact bladder wall.

in some cases, stent insertion may be helpful to address the underlying problem. If unexplained significant, gross hematuria occurs after minor trauma, one should suspect an underlying abnormality of the urinary tract, such as a neoplasm, congenital anomaly, or arteriovenous malformation.

Priapism

Priapism is a prolonged, painful penile erection that occurs in the absence of sexual arousal or stimulation. Priapism is typically divided into ischemic and nonischemic priapism. Important causes of ischemic priapism include sickle cell disease or other blood dyscrasias and certain types of drug or medication use, especially drugs for penile erection and hematologic malignant disease. Nonischemic priapism is the pelvic or genital trauma that results in arteriovenous fistula of the penile circulation. Priapism may resolve spontaneously, but if it persists longer than 4 hours, measures should be taken to reverse the process in most cases. Patients with priapism that lasts longer than 12 hours may develop irreversible damage to the penile vascular structure and long-term ED.

Evaluation in cases of ischemic priapism is centered on detailed history for risk factors, corporal blood gas analysis, and color Doppler ultrasound of the corpora cavernosa. Nonischemic priapism is evaluated similarly; however, aspirated blood has an arterial appearance and arterial blood gas parameters.

Ischemic priapism is managed with initial needle aspiration of the corpora cavernosa and irrigation with saline. In patients who do not respond to this step, needle aspiration is repeated with the injection of small, dilute doses of an α-adrenergic agonist substance, such as dilute phenylephrine. For patients who fail to respond to these measures, various shunting procedures can be performed to create shunts between the corpus cavernosum and other vascular structures, like the corpus spongiosum, to induce blood flow. For priapism related to sickle cell disease, medical treatment of the sickle crisis (e.g., hydration, oxygenation, pain management, and addressing hemoglobin and transfusion status) with hematology support is a mainstay of therapy to resolve priapism. For nonischemic priapism, there is no role for aspiration or irrigation of the erection as this is the result of an abnormality of the vascular system. Compression of the perineum or other injury site can be performed as an initial maneuver. If this fails, the next treatment step is usually superselective angioembolization to occlude the arteriovenous fistula with reversible agents, such as autologous blood clots or Gelfoam. It is important that the general surgeon consult with the urologist about treatment because corporal fibrosis and loss of erectile function are risks that increase with significant delays in therapy.

UROLOGIC INCIDENTALOMAS

There is a wide range of incidental imaging findings that can arise in the urinary system. From an abnormal growth, or "incidentaloma," perspective the most common GU growths are renal tumors or cysts, prostatic abnormalities, bladder thickening, retroperitoneal nodules or nodes, and testicular masses. We will briefly discuss the evaluation, significance, and management of these findings in the following:

- *Renal tumors or cysts:* Indeterminate renal findings can often be seen on renal ultrasounds or cross-sectional noncontrast imaging. The gold-standard evaluation is to obtain cross-sectional imaging in the form of either CT or MRI with contrast. Frequently the incidental findings on initial imaging will turn out to be simple cysts, hyperdense cysts (filled with proteinaceous debris or hemorrhage products), complex cysts usually just requiring follow-up, or a solid enhancing renal mass. If a solid enhancing renal mass is indeed confirmed, then the chances of the growth being malignant is approximately 70% for masses less than 4 cm and 70% to 95% masses over 4 cm depending on the exact size. Most renal masses are less than 4 cm in size, even though they are most likely malignant and tend to have an indolent course with a very long time horizon until metastasis, allowing for time to obtain repeat imaging and specialist referral. Malignancy could be primary renal or a secondary metastatic neoplasm of the kidney from another site, and in the latter case the tumors tend to be more infiltrative and not well circumscribed. Urothelial tumors originating from the collecting system and infiltrating into the renal parenchyma can also appear infiltrative and ill defined. In these situations, it is advantageous to perform a percutaneous renal mass biopsy when there is suspicion for a nonrenal parenchymal tumor. If there is macroscopic fat seen in the indeterminate lesion, this is a hallmark of angiomyolipoma or lipomatous tumors, including liposarcoma.
- *Prostatic abnormalities:* Most incidental prostate abnormalities on cross-sectional imaging are due to BPH with enlarged prostates or prominent intravesical protrusions into the bladder. In the absence of acute urinary symptoms, bilateral hydronephrosis, urinary retention, and active UTIs these findings are not urgent, but if the patient does have one of these symptoms, urologist referral is recommended. In addition, the prostate can frequently show incidental avidity on fluorodeoxyglucose–position emission tomography (FDG/PET) CT scans, and if the patient has a greater than 10-year life expectancy, PSA screening and prostate MRI along with urologist referrals are the next step, as some studies have shown that incidental FDG avidity increases the risk of harboring prostate cancer beyond that indicated by the patient's PSA alone. Given the inflammatory milieu of the prostate, FDG avidity is usually a false-positive finding.
- *Bladder thickening:* Asymmetric bladder thickening is a common finding on CTs and often represents bladder trabeculation from chronic outlet obstruction or motion artifact when the bladder is moving. Concentric bladder thickening is more consistent with bladder outlet obstruction, especially in the presence of diverticula and an enlarged prostate. However, when such findings are present, a urinalysis should always be checked to ensure there is no microscopic hematuria, which would then raise suspicion for neoplasms of the bladder. In addition, bladder thickening in a young male (less than 55 years of age) or a female should also warrant closer observation due to the lower anticipated chance of BPH-related change impacting the bladder. If the bladder thickening is toward the dome of the bladder, where it abuts the anterior abdominal wall and connects to the urachus, this is most likely a urachal remnant. These structures are embryologic vestiges from the allantois, and the chances of them being malignant are very low; however, they could lead to infections or drainage from the umbilicus or into the bladder. Worrisome signs of malignancy of the urachal remnant include an enlarging enhancing 3D mass, gross hematuria, age greater than 65, and calcifications within the mass.
- *Retroperitoneal nodules or nodes:* There is a broad range of pathology that could lead to enlarged retroperitoneal lymph nodes or a retroperitoneal mass, including lymphoma, metastasis from abdominal or pelvic organs, metastasis from testicles,

reactive changes to recent lower extremity or pelvic infections or urinary instrumentation, lymphangiomas, sarcomas, and retroperitoneal fibrosis. However, for an asymptomatic indeterminate sub-centimeter mass without a concurrent testicular mass on exam or ultrasound, and absence of other risk factors such as known personal history of relevant malignancies described earlier, these can usually be observed with close follow-up imaging in 2 to 3 months. For any substantial mass, it is recommended to get tumor markers to rule out primary retroperitoneal germ cell tumor including α-fetoprotein (AFP), beta human chorionic gonadotropin (β-HCG), and lactate dehydrogenase (LDH). In addition, comprehensive cross-sectional imaging with contrast is recommended along with percutaneous corneal biopsy if doubt of the ideology remains.

- *Testicular mass:* The most common type of testicular incidental finding is a cystic fluid collection, which is usually either a hydrocele (which is a fluid collection that develops in between the layers of the tunica vaginalis covering the testicle) or a spermatocele (which is an epididymal cyst). On exam these structures will often transilluminate with an exam light and will also have a discernible fluid wave, but if there is any doubt, then a scrotal ultrasound can be obtained. If these are not bothersome to the patient, as evidenced by lack of pain, tenderness on exam, no overlying skin changes, no history of infection, or no impairment of ambulation due to excessive chafing with thigh skin, then these can simply be observed. If any of these conditions are met, then surgical removal of these fluid-filled structures is a relatively easy outpatient procedure with high success rate. Other sources of incidental testicular findings include inguinal hernias masquerading as spermatic cord or testicular masses. Nevertheless, if there is a solid enhancing lesion along this spermatic cord or in the testicle itself, then a scrotal ultrasound with Doppler should be obtained and the serum tumor markers for testicular germ cell tumors should be checked (again these are AFP, β-HCG, and LDH). The testicular neoplasm evaluation should then be followed, which is discussed in more detail in the following section.

UROLOGIC ONCOLOGY

Urologic malignant neoplasms account for a significant disease burden in adults in the United States. Cancers of the GU system encompass the full spectrum of malignant neoplasms and are some of the most common (prostate) and rare (penile) cancers in the United States. Of the 12 most common cancers diagnosed annually in the United States, 3 are urologic in origin: prostate, bladder, and kidney. Low-stage cancers are typically managed with extirpative surgery or therapeutic radiation. Urologic cancers may involve adjacent viscera, vasculature, and soft tissue and body wall structures so that additional surgical expertise is necessary to complete the extirpative surgery and to support reconstructive efforts. As is the case with other malignant neoplasms, cancers of the GU system are often managed with a multidisciplinary approach. The major anatomic types of urologic cancers are discussed in this section, with a focus on the essential basic background knowledge, the fundamental therapeutic approaches for various stages of cancer presentation, and the basic outcomes for different tumor types.

Renal Cancer

Renal cell carcinoma, the most common type of renal malignant disease, accounts for 2% to 3% of all adult malignant neoplasms.[31] The majority (>50%) of renal malignant neoplasms are now diagnosed incidentally by cross-sectional imaging or ultrasound evaluation of other nonspecific complaints. Historically, renal cell carcinoma was diagnosed only at an advanced stage because of its location within the retroperitoneum. The classic triad of renal cell carcinoma (flank pain, gross hematuria, and palpable abdominal mass) is now seen in less than 5% of patients. Despite this increase in asymptomatic diagnoses, 30% of patients present with metastatic disease.[32] Other symptoms on advanced presentation include hemorrhage, paraneoplastic syndrome, and symptoms of metastasis, such as pathologic fracture. Paraneoplastic syndromes are present in 20% of patients at diagnosis and include Stauffer syndrome (reversible hepatitis without liver metastasis), constitutional symptoms, anemia, polycythemia, and elevated inflammatory markers (erythrocyte sedimentation rate and C-reactive protein).[32] Renal cell carcinoma typically presents in the sixth to eighth decade of life and is more common in males. Risk factors for renal cell carcinoma include smoking, hypertension, obesity, acquired renal cystic disease (in patients with end-stage renal disease), and occupational exposures (aromatic hydrocarbons, asbestos, cadmium, and chemical and rubber industries).[31] These tumors typically arise in the proximal convoluted tubule or collecting duct within the renal parenchyma.[31]

Renal cell carcinoma is classified as follows: clear cell carcinoma, papillary renal cell carcinoma, chromophobe renal cell carcinoma, collecting duct carcinoma, and renal medullary carcinoma. This classification is based on microscopic appearance and cell of origin.[31] The genetics of these malignant neoplasms is fairly well described. The most common tumor histology, clear cell carcinoma, which is observed up to 85% of the time, is the result of chromosome 3 abnormalities; papillary carcinoma is the result of aberrations of chromosome 7, 17, or Y.[31] In addition, clear cell carcinoma and papillary carcinoma are responsible for the two most common familial cancer syndromes, von Hippel-Lindau and hereditary papillary renal cell carcinoma, respectively. Most renal masses are malignant, and only 15% to 20% are benign; the two most common benign masses are oncocytoma and angiomyolipoma.[32]

A final consideration with renal neoplasms is cystic renal masses, which present diagnostic challenges. Depending on specific characteristics of renal cystic lesions, the risk of these lesions representing cystic malignant neoplasms must be considered. The Bosniak classification system describes cystic renal masses according to their malignant risk and CT appearance, ranging from category I (simple cysts, 0% risk of malignancy) to category IV (cysts associated with enhancing or solid elements, 70% risk of malignancy).[31] Category III and IV cysts are usually treated as representing renal cell carcinomas.

Staging

Outcomes in renal cell carcinoma are directly tied to clinical stage at time of diagnosis. Evaluation and staging for renal cell carcinoma include history, physical examination, and laboratory testing. Evaluation for renal masses includes imaging of the primary tumor, usually with a contrast-enhanced CT scan or MRI study of the abdomen and pelvis as well as chest imaging, typically chest radiography. Also, based on clinical suspicion or abnormal results of laboratory studies, bone and brain imaging is performed. A key aspect of abdominal CT or MRI is evaluation of the renal vein and inferior vena cava as locally advanced renal cell carcinoma commonly forms tumor thrombus in these structures. The TNM staging system is listed in the *American Joint Committee on Cancer*

(AJCC) Cancer Staging Manual.[33] Histologic grading is based on the Fuhrman nuclear grading system on a scale of I to IV.

Management

The management of renal cell carcinoma has evolved in recent years. Historically, renal cell carcinoma was a surgical disease, and patients diagnosed with any renal mass underwent total radical nephrectomy. Now, select patients may undergo renal biopsy and active surveillance protocols. In the past, renal biopsies were fraught with high false-negative rates and low accuracy. Contemporary series show an accuracy rate of more than 90% in experienced centers with low complications and no reported incidence of tumor seeding when using the core-needle biopsy technique.[32] Those patients who are appropriate for renal biopsy are patients considered for either active surveillance or renal ablation therapy. Active surveillance protocols have been developed for patients with incidentally diagnosed, small (<2 cm) renal masses and those patients who would not tolerate extirpative or ablative therapy.[32] The natural history of small renal masses is a tendency to grow slowly, on average 0.5 cm/year, and they do not metastasize. Patients assigned to surveillance protocols undergo imaging every 6 months; once mass size stability is observed, this interval is extended to 6 to 12 months.[32] Small renal masses (<3 cm) can be considered for percutaneous, laparoscopic, or open ablation using cryotherapy or radiofrequency energy.[31] This treatment should be considered more for patients with significant medical comorbidities and less often in healthy patients.

For organ-confined renal tumors, extirpative surgery is the standard approach. For renal cancer with limited metastatic disease, cytoreductive nephrectomy has been an option with possible resection of metastatic lesions. However, the benefits seen with new systemic therapies are changing this paradigm. Minimally invasive surgery, both robotic and laparoscopic techniques, are standard for most renal lesions. The trend in extirpative surgery is to perform nephron sparing or partial nephrectomy for most T1 tumors. Partial nephrectomy is equivalent to radical nephrectomy in this tumor stage and should be considered for all patients with a T1a tumor and most with T1b tumors. Partial nephrectomy surgery may be straightforward in dealing with small, well-encapsulated, superficial, exophytic lesions or complex in dealing with larger, central lesions that involve the renal hilar structures. For partial nephrectomy, a negative margin should be obtained with the parenchymal resection, and only a few millimeters of normal parenchyma around the tumor are considered necessary. The general principles for partial nephrectomy include achievement of a negative surgical margin, identification and suturing of significant segmental renal vessel branches, and collecting system repair when the collecting system is entered or partially resected. To assist with blood loss, atraumatic vascular clamping of the renal artery and surface cooling of the kidney with iced saline slush are effective. When laparoscopic or robotic approaches are used for partial nephrectomy, local hypothermia is not possible; therefore, rapid tumor resection and clamp times of less than 35 minutes are employed. Tissue sealants, hemostatic agents, and absorbable mesh reconstruction of the kidney are all useful techniques to aid in hemostasis of a partial nephrectomy in the open surgical, laparoscopic, or robotic setting.[32]

Radical nephrectomy is performed in patients with large or multifocal tumors and those patients in whom a partial nephrectomy is not technically feasible. The primary long-term risk in this surgery is acute and chronic decline in renal function. Compared with partial nephrectomy, radical nephrectomy has a lower rate of complications. The adrenal gland is no longer removed with radical nephrectomy except in cases of obvious tumor involvement as the rate of synchronous involvement is less than 10%. Typically, radical nephrectomy is performed by either a laparoscopic or an open approach. Standard incisions for radical nephrectomy include anterior subcostal, flank, chevron, and midline. Regardless of approach, dissection of the renal pedicle with ligation of a renal artery must precede vein ligation to prevent swelling and dangerous bleeding from the kidney. The entire Gerota fascial envelope, containing the perinephric fat as a margin around the kidney parenchyma and tumor, is excised intact. The ureter is ligated and divided where convenient.[31] A regional lymph node dissection may be performed with a radical nephrectomy, although, on the basis of most evidence, it is more helpful as a staging and prognostic procedure than as a therapeutic one.[34]

Thermal ablation, which is an option for T1a renal masses smaller than 3 cm in diameter, was developed in an effort to improve patient procedural tolerance and reduce the complications from partial nephrectomy while still preserving function. Radiofrequency and cryoablation have been the most widely investigated and integrated into clinical practice, and oncologic outcomes are similar for both approaches even though long-term data for thermal ablation is still pending. Thermal ablation can be accomplished through open, laparoscopic, or percutaneous (most common) approaches. Thermal ablation can also be repeated if persistent viable malignancy is suspected.

For patients with locally advanced or metastatic disease, immunotherapy and targeted therapy (drugs with action on vascular endothelial growth factor and mammalian target of rapamycin) are used in a neoadjuvant or adjuvant setting. Overall organ-confined disease has an 80% to 100% 5-year survival in T1 tumors and a 50% to 80% 5-year survival in T2 disease.[32] Advanced disease has a grim prognosis of 0% to 20% 5-year survival.[32]

Several adjuvant kidney cancer trials have explored the potential benefit of systemic therapies after surgical resection of high-risk disease and has shown some benefit, particularly with pembrolizumab. For patients with metastatic disease, the landscape of systemic therapy for metastatic renal cell carcinoma is rapidly evolving, and options range from the more established targeted therapies to the newer regimens that include immunotherapies.[31,33]

Bladder Cancer

Urothelial malignant disease can arise anywhere in the upper or lower collecting system, but the most common site is the bladder. The entire upper and lower urinary tracts (renal collecting system through the distal urethra) are lined with surface epithelium called urothelium. The urothelium has a variable thickness of three to six cell layers, and transitional cell carcinoma arises from the basal cell layer. Bladder cancer is the fifth most common adult malignant neoplasm diagnosed in the United States and is more common in males than in females, in part, related to impaired bladder emptying in males with increasing age.[35] The tumor arises most frequently in the eighth decade of life, and males older than 70 years have a 3.7% probability for development of bladder cancer.[35] The multiple risk factors for development of bladder cancer include tobacco smoke, arsenic, chronic infections and inflammatory conditions (e.g., schistosomiasis), and occupational exposures (such as arylamines and aromatic hydrocarbons). The most common presenting symptom in bladder cancer is hematuria, microscopic in 1% to 11% and gross in 13% to 35%.[35] Importantly, a single episode of gross hematuria, especially in smokers, can carry a significant risk of cancer and warrants a full workup. Microscopic hematuria, on one urinalysis microscopy, qualifies a patient for a workup, but the risk of cancer depends greatly on other risk factors and patient factors. The other presenting symptom is irritative voiding (frequency, urgency, and dysuria) in the absence of infection on urine culture.

Bladder cancer is separated into nonmuscle invasive bladder cancer (NMIBC) and muscle invasive bladder cancer (MIBC), and each arises from different molecular pathways and has different treatments and outcomes. Urothelial tumors that have not invaded the detrusor muscle are termed NMIBCs. Approximately 70% of patients who present with bladder cancer will be diagnosed with NMBIC, which includes T stages Tis (carcinoma in situ [CIS]), Ta, and T1.[36] The other 20% to 40% of will either present or progress to MIBC includes stage T2 or higher bladder cancer at diagnosis.[37,38] TNM staging is included in the *AJCC Cancer Staging Manual*[37]; the T stage at diagnosis, specifically nonmuscle invasive (T1 or less) or muscle invasive (T2 or higher), is highly predictive of long-term outcome and survival. Ta disease refers to papillary tumors, with involvement of only the mucosa. T1 tumors involve the lamina propria, and T2 disease involves the detrusor muscle. Higher stages of the local tumor reflect involvement of perivesical fat or adjacent organs. Tumors are graded on the basis of histologic appearance from papilloma to high grade.

Nonmuscle Invasive Bladder Cancer

Patients who are suspected of having bladder cancer should undergo a thorough evaluation, which includes history, physical examination, basic laboratory tests, upper urinary tract imaging (preferably contrast-enhanced cross-sectional imaging), and office cystoscopy. If bladder cancer is present, characteristic flat, papillary, or large, sessile, aggressive-appearing masses will be present on the urothelial surface of the bladder. NMIBCs typically appear as flat (CIS) or papillary (Ta or T1) lesions.[36] An adjunct test for identification of bladder cancer is use of urine cytology, which is either as voided or bladder wash at the time of cystoscopy. Urine cytology is most sensitive for high-grade tumors and can be equivocal or nondiagnostic in the setting of low-grade NMIBCs. Adjunct urine tumor markers exist but are not recommended on consensus guidelines because of cost and low specificity.[37]

Any tumor identified in the bladder should be fully resected by TURBT. TURBT is diagnostic, by providing pathologic analysis, tumor staging by identification (if present) of muscle invasion, and potentially therapeutic in treatment of noninvasive disease. TURBT is performed through a surgical endoscope, called a resectoscope, and uses either monopolar or bipolar energy to shave the tumor from the bladder wall alongside continuous irrigation.[35] At the time of TURBT, patients should undergo a bimanual examination of the bladder. A palpable mass after TURBT represents extravesical extension (T3) of tumor, and, if the lesion is fixed, it raises the possibility of pelvic sidewall or adjacent organ invasion (T4). Any patient identified with high-grade tumors with any possibility of incomplete first resection or absence of muscle in the initial resection should undergo repeated TURBT within 2 to 6 weeks.[36]

Immediate intravesical chemotherapy refers to intravesical administration of an antineoplastic agent within 24 hours of TURBT, which has been shown to reduce the tumor recurrence by 35%. The agent most commonly used for this purpose is mitomycin C with many centers transitioning to gemcitabine for better patient safety.[36] In a patient with low- or intermediate-risk bladder cancer, a clinician should consider administration of a single postoperative instillation of intravesical chemotherapy.[35] Six weeks after TURBT, patients with CIS or NMIBC with high risk for progression or recurrence or CIS should receive intravesical therapy with either immunotherapy or chemotherapeutic agents. Standard immunotherapy for NMIBC consists of serial bacille Calmette-Guérin (BCG) intravesical instillations for induction and periodic maintenance therapy. Intravesical BCG significantly decreases the invasion and progression rate for NMIBCs, compared with transurethral resection alone. Maintenance BCG instillations reduce the risk of recurrence and progression and are given at variable intervals for periods of 1 to 3 years.[36] If a patient's cancer is unresponsive to BCG and the tumor recurs, there are many salvage intravesical therapies being investigated but the gold standard remains radical cystectomy. Periodic surveillance by office cystoscopy and upper tract imaging is mandatory in these patients as 60% to 80% of these tumors recur, and in higher grade tumors, 10% to 20% progress to higher stage or muscle invasive tumors.[36] Enhanced cystoscopy using blue light technology with hexaminolevulinate or narrow-band imaging may improve detection and lower recurrence rates.[35]

Muscle Invasive Bladder Cancer

The majority of patients who present with MIBC have invasive disease at diagnosis, and it has a much higher risk of progression and metastasis.[35] These cancers are highly lethal and are the cause of death in the vast majority of patients within 2 years of diagnosis without aggressive treatment. Approximately 70% of patients present with localized disease, whereas 33% have regional spread and 5% have distant metastasis at the time of diagnosis.[39] MIBC is typically urothelial cell carcinoma, but other histopathologic types occur, including squamous cell carcinoma, adenocarcinoma, and small cell carcinoma, with potentially worse outcomes. MIBC should be staged in a similar fashion to NMIBC, with cross-sectional imaging of the abdomen and pelvis, but consideration should be given to chest CT rather than plain radiography. Despite adequate staging, 40% of patients are understaged at diagnosis and have extravesical disease on the final pathologic specimen.[39]

Management

Standard management of MIBC is radical cystoprostatectomy in males and cystectomy in females, combined with neoadjuvant cisplatin-based chemotherapy for all eligible patients. In the male patient, radical cystectomy involves the removal of the entire urinary bladder en bloc with the perivesical fat, prostate, seminal vesicles, and pelvic lymph nodes. In the female patient, radical cystectomy typically involves en bloc removal of the female pelvic viscera (uterus, cervix, fallopian tubes, and the anterior vagina), although preservation of these structures may at times be considered, depending on the details of the case. Extended lymph node dissection is performed at the same setting and includes removal of the external and internal iliac lymph nodes, common iliac lymph nodes to the aortic bifurcation, and presacral lymph nodes. Improved survival is associated with extended pelvic lymph node dissection at the time of radical cystectomy. Perioperative complication rates are high, and more than 60% of patients undergoing radical cystectomy and extended pelvic lymph node dissection have at least one complication within 90 days of surgery.[39] Because of the high rate of extravesical extension at the time of radical cystectomy, and based on level 1 evidence, neoadjuvant chemotherapy is employed with overall and recurrence-free survival benefits. Typical regimens for neoadjuvant chemotherapy include methotrexate, vinblastine, doxorubicin [Adriamycin], and cisplatin (MVAC) or gemcitabine and cisplatin (GC). The use of neoadjuvant chemotherapy improves overall survival by 5% to 7%.[39] Adjuvant chemotherapy is offered to patients with high-risk pathologic features from surgery with no evidence of metastasis, and retrospective data support its use, with prospective trials currently in progress. A challenge of relying on adjuvant chemotherapy is that the recovery after cystectomy can often delay timely initiation of therapy.[39] Following cystectomy, patients with organ-confined, node-negative disease have the best overall disease-specific survival at 5 and 10 years at 85% and 60%, respectively. Neoadjuvant chemotherapy achieves a pT0 rate twice as often as surgery alone, and this confers a dramatic improved survival as well. Patients with extravesical disease have 5-year disease-specific survival in the 50% range, whereas patients with node-positive disease who have undergone a thorough lymph node dissection have a 30% 5-year disease-specific survival.[39]

The selection of the type of urinary diversion after radical cystectomy must take into account any history of pelvic irradiation, presence of renal insufficiency, liver function abnormalities, and mechanical tasks for which the patient will be responsible. There are various options for urinary diversion, including ileal conduit, orthotopic bladder substitution with anastomosis to the native urethra (neobladder), and more complex forms of cutaneous catheterizable reservoirs with continence mechanisms. No randomized study has shown one type of urinary diversion to be superior to any other, and the decision is usually directed by the patient's preference or the surgeon's choice. There is an extensive and complex history involving the use of intestinal segments in the urinary tract for urinary diversion after cystectomy and in other reconstructive settings. The surgeon should be familiar with the metabolic, mechanical, and other risk factors associated with the use of intestinal segments in the reconstructed urinary tract, including electrolyte abnormalities, bone demineralization, mucus production, stone formation, chronic infection, diarrhea, vitamin B_{12} deficiency, and increased cancer risk.[39]

Prostate Cancer

Prostate cancer is the most common cancer diagnosed in males and the third most common cancer diagnosed in the United States, behind breast and lung cancer, with approximately 240,000 males diagnosed annually resulting in approximately 30,000 deaths.[40] Prostate cancer is an adenocarcinoma and arises from the glandular structures within the prostatic parenchyma. Most new prostate cancer cases are diagnosed in males 60 years of age and older, are low grade and low stage, and are diagnosed by routine screening.[41] Screening for prostate cancer is performed with the blood test PSA, a serine protease, and DRE. The most controversial aspect of prostate cancer is screening and determining which patients require treatment. The goal of prostate cancer screening is to detect potentially lethal cancer at an early, treatable stage and to intervene with intent to cure. Because of the controversy surrounding the recent US Preventive Services Task Force (USPSTF) recommendation against screening for prostate cancer in 2012, the AUA released its own guidelines for screening in 2013. The USPSTF released revised guidelines in 2018.[40] These recommendations are for screening in males aged 55 to 69 years to be a joint decision between the physician and the patient, and a routine screening interval to occur every 2 to 4 years.[40] More intensive evaluation should be considered in males with a strong family history and genetic predisposition and those who are African American. Routine screening is not routinely recommended in males less than age 40 and in males older than 70 years. Current AUA guidelines state to start PSA screening between ages 40 and 45 for patients at increased risk and 45 and 50 for patients at average risk.[40,42] Furthermore, screening should not be performed in males with a life expectancy of less than 10 to 15 years.

Evaluation

Patients who have either an elevated total PSA level or abnormal findings on DRE or both undergo TRUS-guided biopsy of the prostate. Additional serum and tissue tests and MRI imaging can be combined with basic data to risk-stratify a male before or after biopsy. The standard biopsy template involves 12 cores with a spring-loaded biopsy instrument; tissue is obtained from the base, mid, and apex regions, medially and laterally from the left and right sides. Prophylactic antibiotics are routinely administered, and cleansing enemas are advised. When feasible, patients are asked to stop anticoagulants to help prevent bleeding complications. Common adverse events that follow TRUS biopsy include rectal bleeding, gross hematuria, and hematospermia, all of which are usually self-limited. Fever and urinary infection and retention occur in less than 5% of patients; bacteremia occurs, but it occurs in less than 1% to 3% of patients.[40]

Prostate cancer is diagnosed histologically by the Gleason grading system, which evaluates the level of abnormality in the patterns of the glandular architecture of the prostate compared with normal. The grading system is based on a scale of 1 to 5, with 1 being the most well differentiated and 5 being the least well differentiated. In the modern PSA-based screening era, prostate cancers have a Gleason grade minimum of 3 with a sum of 6 or greater, and the majority of newly diagnosed cancers are Gleason 3+3. Patients diagnosed with prostate cancer are risk-stratified on the basis of PSA level at time of diagnosis, clinical stage based on DRE, and Gleason sum score on the prostate biopsy.[42] Patients with unfavorable intermediate- and high-risk cancers should undergo cancer staging, which in prostate cancer may include radionuclide bone scan or more recently a prostate-specific membrane antigen (PSMA) PET CT to evaluate for bone metastasis and cross-sectional imaging of the abdomen and pelvis to evaluate for nodal metastasis.[42]

Treatment

The treatment of prostate cancer has changed significantly during the last two decades. Shared decision-making takes into account cancer details, patient medical factors, life expectancy, and patient preference to determine the preferred mode of treatment. As most prostate cancer is low risk at diagnosis, many patients (up to 50% in certain centers) are now managed with active surveillance rather than with definitive therapy. In general, males with cancer of low clinical stage (<T2a), low grade (Gleason sum ≤6), low PSA (<10 ng/mL), and low volume on biopsy are candidates for active surveillance. Patients assigned to active surveillance protocols undergo DRE and PSA monitoring every 3 to 6 months, often incorporating MRI at certain intervals and repeated TRUS-guided prostate biopsies every 1 to 3 years. Patients with increase in Gleason sum or increase in tumor volume on biopsy typically shift to an active treatment plan, and up to 25% of males on active surveillance go on to definitive therapy within 5 years.

Prostate cancer can be treated with either radical surgical excision or definitive radiation therapy. Radical prostatectomy involves the surgical removal of the entire prostate and seminal vesicles with anastomosis of the urethral stump to the bladder neck. The extent of bilateral pelvic lymph node dissection is based on extent of disease and risk group of the cancer. For prostate cancer Gleason sum 8 or higher, at a minimum, the external iliac, internal iliac, and obturator lymph nodes should be removed. Radical prostatectomy can be performed with an open, laparoscopic, or robotically assisted laparoscopic approach. The majority of cases in the United States are now performed by a robotic-assisted laparoscopic approach prostatectomy (RALP). The advantages of RALP have been reported to be decreased blood loss, shorter hospital stay, and quicker return to work. When it is technically feasible and oncologically appropriate, a nerve-sparing approach is used, which avoids injury to the cavernous nerves that run posterolateral along the prostate in the neurovascular bundle and mediate penile erection. Important landmarks for radical prostatectomy are the dorsal venous plexus anteriorly, bladder neck cephalad, prostatomembranous urethral junction distally, and rectal wall posteriorly. The correct plane of posterior dissection in radical prostatectomy is just posterior to the Denonvilliers fascia. The primary long-term risks of radical prostatectomy are urinary incontinence and ED. Ten-year cancer progression-free survival is approximately 85% for patients with organ-confined disease, approximately 60% to 70% for patients with extracapsular extension, and approximately 50% for patients with positive surgical margins.[42]

Patients who do not desire or who are not candidates for surgical extirpation may undergo local therapy with either intensity-modulated radiation therapy (IMRT) or brachytherapy. The typical treatment dose for IMRT-based prostate cancer therapy is 76 to 86 Gy. The most common form of brachytherapy is low-dose ultrasound-guided placement of iodine-125 or palladium-103 radioisotope sources into the prostate. Both treatments are commonly used for low-risk prostate cancer. Intermediate- and high-risk prostate cancer is typically treated with IMRT coupled with androgen deprivation therapy for up to 3 years. Low-, intermediate-, and high-risk prostate cancers have cancer survival outcomes after radiation-based therapy similar to those of radical prostatectomy.[42]

In advanced prostate cancer, the standard approach with androgen deprivation therapy may become ineffective, with clinical or PSA progression observed in spite of appropriate hormonal blockade. When castrate-resistant disease develops, second-line treatment includes antiandrogens, chemotherapy, and investigational agents. Other forms of treatment considered for local treatment of prostate cancer include ablation, such as high-intensity frequency ultrasound and cryotherapy, and proton beam therapy, although long-term results for these modalities are still being reported. Focal therapy of discrete lesions is also being studied in clinical trials, but outcomes and surveillance with focal therapy are uncertain due to the commonly multifocal nature of prostate cancer. It remains a modality that should be confined to clinical trials.[41,42]

After prostate cancer therapy, patients are monitored for post-treatment morbidities (e.g., continence, erectile function, voiding adequacy) and possible cancer recurrence. The latter involves PSA testing and potentially repeated metastatic evaluation, when indicated. Long-term follow-up for prostate cancer patients should continue at least 10 years, if not permanently, because very late recurrences can occur. If the PSA level becomes significantly detectable or is rising after definitive treatment, imaging with PSMA PET CT is needed to rule out metastasis. Options to decide whether to proceed with local radiation therapy, androgen deprivation therapy, or observation. Dramatic improvements in prostate cancer survival have been achieved in the last two to three decades, due to improved detection with screening and major advances in systemic treatment of metastatic disease.[42]

Testicular Cancer

Testicular cancer is an uncommon malignant neoplasm; in the United States, the incidence is 5/100,000 males.[43,44] Most cases of primary testicular cancer are germ cell origin (95%); the remainder are predominantly stromal (Leydig cell) or sex cord (Sertoli cell) tumors.[43,44] Any solid intratesticular mass is likely to represent a malignant germ cell tumor and is typically treated as such unless there is a strong suspicion to the contrary. Risk factors for testicular tumors include Scandinavian descent, cryptorchidism, orchitis, family history of testicular cancer, and intratubular germ cell neoplasia.

Germ cell–derived testicular tumors can be broadly divided into pure seminoma and mixed nonseminoma germ cell tumors (NSGCTs), and the division is approximately 50% for each. The majority of seminomas histologically are classic (85%); the remainder are either anaplastic or spermatocytic seminoma.[43] NSGCTs can be divided into numerous histologic types: embryonal carcinoma, yolk sac or endodermal sinus tumors, choriocarcinoma, teratoma, and mixed germ cell tumors. Testicular malignant neoplasms are the most common tumors in males between the ages of 20 and 40 years.[43] Seminomas, however, have a bimodal distribution with a second peak present in the fourth or fifth decade of life, and spermatocytic seminomas may present in males older than 50 years.[43] The most common presenting complaint in males with testicular cancer is a painless testicular mass; however, symptoms of metastatic disease include back pain, palpable abdominal mass, shortness of breath, or hemoptysis. In patients who present with a painless testicular mass, scrotal ultrasonography is the diagnostic study of choice. In addition to history, physical examination, and ultrasonography, patients with testicular tumors should have determination of specific tumor markers: AFO, β-HCG, and LDH. Each of these markers has a characteristic half-life, and they are important for initial cancer staging and surveillance.

Treatment

Initial treatment of suspected testicular tumor is radical inguinal orchiectomy, which involves removal of the testicle and spermatic cord at the level of the inguinal ring (Fig. 121.13). Because of the characteristic and well-described lymph drainage of the testicle, there is no role for transscrotal biopsy or orchiectomy. If the intrascrotal tissue planes are violated during orchiectomy, the lymphatic drainage can be altered, affecting future treatment. Before or after radical inguinal orchiectomy, the patient should undergo disease staging, including cross-sectional, contrast-enhanced imaging of the abdomen and pelvis and chest imaging, either chest radiography in low-risk patients or cross-sectional chest imaging in patients with high-risk disease.

Clinical staging for testicular cancer includes primary tumor pathology, lymph and metastatic staging on imaging, and postorchiectomy serum tumor markers. The half-life of β-HCG is 24 to 36 hours, and the half-life of AFP is 5 to 7 days; these levels should normalize in the absence of metastatic disease. Metastatic disease from testicular cancer follows a predictable retroperitoneal lymphatic spread, skipping the inguinal and pelvic nodal stations, given the testes' embryologic origin and corresponding vascular drainage. Choriocarcinoma is notorious for hematogenous spread early to distant sites. From the right testis, initial lymph node metastasis is to the infrarenal interaortocaval nodes, paracaval

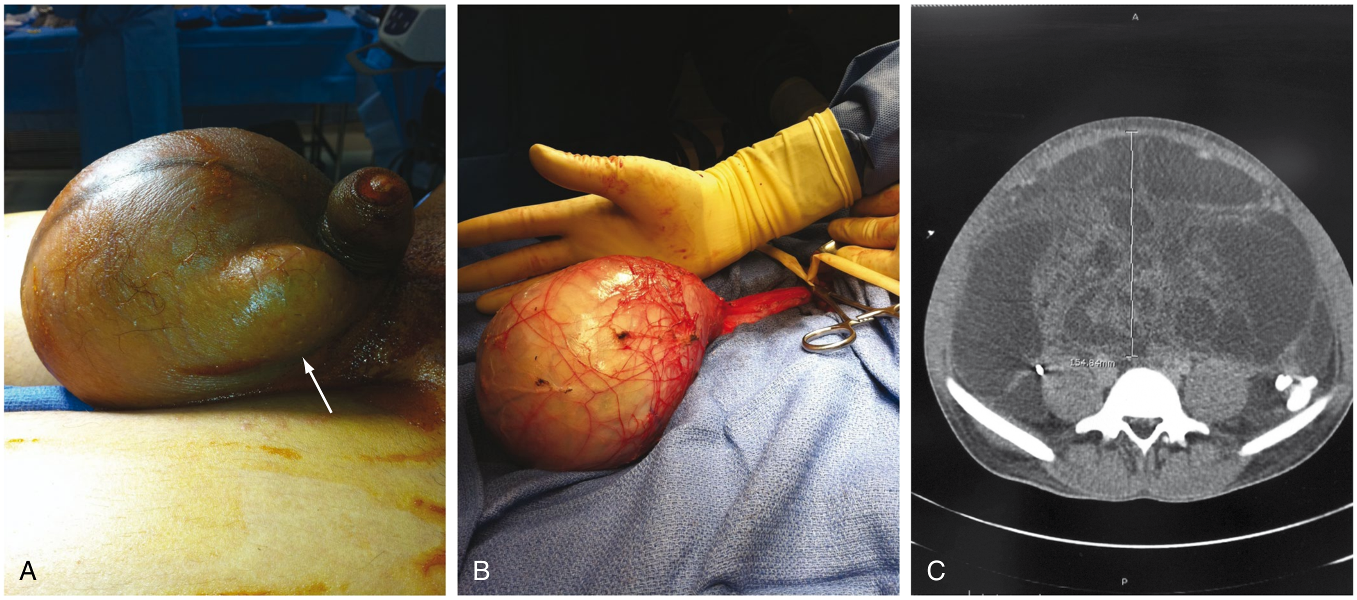

FIGURE 121.13 Advanced testicular carcinoma. (A) Preoperative appearance of the scrotum in a patient with a large right testis tumor. The normal left testis is seen pushed cephalad by the right-sided mass. (B) Surgical exploration through right inguinal incision showing the right testis that has been dissected from the scrotum in an extravaginal plane still attached by the spermatic cord pedicle to the right. (C) Massive retroperitoneal lymphadenopathy in the same patient. Note that the descending colon is opacified with contrast material, but all other viscera are pushed cephalad so that no small intestine is seen in this image. The patient was managed with primary chemotherapy followed by retroperitoneal lymphadenectomy for the residual mass.

nodes, and paraaortic nodes, and on the left, the paraaortic nodes and then interaortocaval nodes. Retroperitoneal lymph nodes are the primary metastatic site in more than 70% of patients with metastatic testicular cancer.[45] If the patient has had prior groin or pelvic surgery, the natural lymphatic distributions may be altered and the metastatic pattern may be unpredictable, potentially leading to involvement of the inguinal or pelvic nodes. Distant metastases are typically seen to the lung, liver, brain, bone, kidney, and adrenal gland.

Second-line treatment is directed by tumor histology and lymph node staging. Further treatment may consist of regular surveillance, retroperitoneal radiation therapy, retroperitoneal lymph node dissection (RPLND), systemic chemotherapy, or a multimodal therapy approach. The treatment decisions are complex, often at the direction of an institutional tumor board, but several general principles apply[45]:

- For seminoma stage IA and IB disease, treatment options include surveillance, radiotherapy to the regional (paraaortic) lymph nodes (20 Gy), and one cycle of carboplatin-based chemotherapy.
- For seminoma stage IIA and IIB, radiotherapy of the retroperitoneal lymph nodes is standard therapy, but RPLND is now being added based on recent studies[46]; for stage IIC or III, platinum-based chemotherapy is standard therapy.[44,45]
- For NSGCT stage I disease, the options include surveillance, primary RPLND, or cisplatin-based chemotherapy.[45]
- For NSGCT stage IIA, either primary RPLND (in patients with normal levels of tumor markers) or three or four cycles of cisplatin-based chemotherapy is standard; for stage IIB, three or four cycles of cisplatin-based chemotherapy is standard.
- For NSGCT stage III, treatment consists of cisplatin-based chemotherapy.

RPLND (Fig. 121.14) involves removal of all lymph nodes in the retroperitoneum from the renal vessels to the aortic bifurcation. An appropriate RPLND should include the lymph tissue surrounding the great vessels and division of the appropriate lumbar vessels to ensure thorough dissection using the split-and-roll technique. The most challenging RPLNDs are after chemotherapy, when the retroperitoneal tissues may be fibrotic or desmoplastic and adherent to the inferior vena cava, aorta, bowel, and mesentery. RPLND is template driven, and the appropriate levels and location of tissue excision are well described. Following the appropriate templates, the sympathetic nerve chain should be

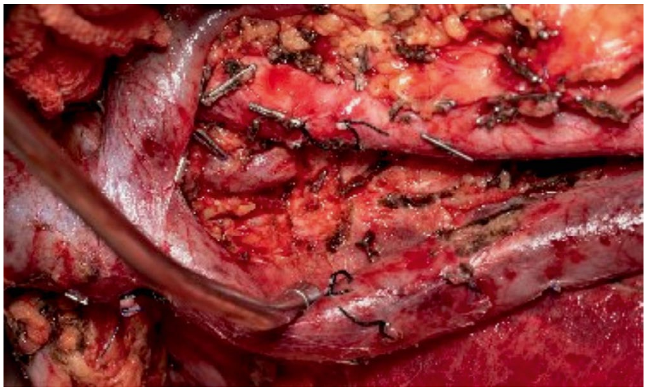

FIGURE 121.14 Right-sided retroperitoneal lymph node dissection with inferior vena cava and left renal vein skeletonized and the underlying caval nodes removed. The anterior longitudinal ligament of the spine can be seen. The interaortocaval and some of the preaortic lymph nodes have been removed. The remaining lymph nodes were addressed by reflecting the left colon.

uninjured, allowing antegrade ejaculation. Extensive dissection in this territory often induces an autonomic reaction with persistent tachycardia, which may last for an extended period (4–6 weeks).

Many patients undergoing RPLND will have been exposed to bleomycin chemotherapy, which requires meticulous intraoperative anesthetic management because of the exquisite sensitivity of these patients to elevated oxygen exposure; often, the anesthetic is run essentially on room air ventilation in these cases.

Patients should be made aware of the potential impact of radiation, chemotherapy, or RPLND on the ability to ejaculate and on spermatogenesis. It is essential that patients be offered sperm cryopreservation after orchiectomy and before therapies that could adversely affect their reproductive potential. In addition, patients should be made aware that radiation has the potential morbidity of delayed secondary malignant disease as high as 15% within 25 years of treatment.[45]

Curative treatment of testicular cancer is one of the great success stories of modern oncology. Overall, long-term survival for testicular cancer ranges from 98% to 99% for stage I seminoma or NSGCT.[45] In patients with stage II seminoma, radiotherapy yields survival of up to 100%, and stage II NSGCT standard treatments yield survival of 90% to 95%.[45] Even advanced disease, stage III seminoma, has an expected survival of more than 90%, and NSGCTs have long-term survivals of 80% to 90%.[45]

Given the high survival rates, late- or long-term toxicities of treatment must be monitored, including early cardiovascular disease and metabolic syndrome from chemotherapy and secondary malignancies as mentioned.
